Summary

We study the effect of long-term care (LTC) subsidies and supports on the wellbeing of unpaid caregivers. We draw on evidence from a policy intervention, that universalized previously meanstested caregiving supports in Scotland, known as *free long-term care* (FPC). We document causal evidence of an increase in the well-being (happiness) of unpaid carers after the introduction of FPC. Our estimates suggest economically relevant improvements in the happiness (12pp increase in subjective wellbeing) among caregivers exposed to FPC and that provide at least 35 hours of care per week. Consistently, these results are larger among women and non-actively employed caregivers (17pp increase in happiness). Estimates are not driven by selection into caregiving (we find similar wellbeing effects among caregivers from the beginning and caregivers throughout the sample), and are driven by income effects of FPC among caregivers.

Keywords: caregiving, long-term care subsidies, subjective wellbeing, caregiver's wellbeing, Scotland.

JEL: 118, J22.

1. Introduction

Some studies have documented that unpaid caregiving is responsible for both emotional and monetary losses, including opportunity costs of time (forgone employment and earnings) from the provision of care which reflects in several dimensions of wellbeing (van den Berg *et al* 2014; Rattinger *et al.*, 2015; Leggett *et al*, 2018). However, there is still fairly limited consensus in the literature, and a metanalysis of previous evidence finds both positive and negative effects of caregiving, although still, the negative effects are more prominent among lower-income individuals (Pinquart and Sorensen, 2003). Other studies even document that caregiving can explain up to 50% of the total costs of dementia among caregivers (Hurd *et al*, 2013), and is documented to increase the use of antidepressants, tranquillizers, painkillers and gastrointestinal agents (Schmitz and Stroka, 2013; Stroka, 2014). However, most estimates in the literature are mostly not causal, namely caregiving decisions are not the result of an exogenous variation in caregiving conditions. A common strategy to retrieve causal estimates lies in examining the effect of policy interventions that exogenously change the conditions under which caregivers provide care¹.

Subsidies that free some caring time or provide financial respite to the care-receiver can impact caregivers wellbeing. Proponents of cash subsidies argue that they increase care-receivers' choice and quality of care (Simon-Rusinowitz *et al.*, 1998), by allowing family members to deliver personal care at home (Mahoney *et al.*, 2002). For example, some studies suggest evidence of emotional, physical, and financial wellbeing improvements after the introduction of the Cash and Counseling Demonstration and Evaluation (CCDE) program which entailed flexible monthly allowances for Medicaid beneficiaries to hire informal caregivers as paid workers (Foster *et al.*, *al.*, *al.*,

¹ Alternative strategies use instrumental variables to estimate a local average treatment effects, using within household variation in the presence of a single parent (Heger, 2017).

2003). A growing literature has focused on the effect of long-term care (LTC) subsidisation, on care choices and household behaviour (McKnight, 2006). However, we still know little about the extent to which the expansion of caregiving supports , influence the wellbeing of carers.

This paper examines the causal effect of a specific policy intervention, which resulted from the implementation of the Scottish Community Care and Health Act (CCHA), which universalised the access to care, by offering free personal care (FPC), namely, establishing a network of supports and services to the Scottish population after 2002². This reform eliminated the pre-existing means tests for personal care to individuals with caregiving needs. The fact that subsidies remained meanstested in the rest of the United Kingdom (UK), constitutes a natural control group. Next, we consider a number of robustness checks, including evidence that documents that the reforms were driven by individuals that were providing care at baseline (i.e., from the begining), and finally, we show a number of mechanisms explaining the channels of the effect.

We contribute to the literature by retrieving causal estimates of the effects of FPC on caregivers' wellbeing and their mental health. Given that caregiving supports can influence both the decision to become a caregiver, alongside the intensity of caregiving duties, we estimate the effect of caregiving subsidies and supports on caregivers wellbeing at baseline, as well as the total effect. This complements previous findings indicating that caregiving increases depression in different countries and settings (Hiel *et al.*, 2015; Heger, 2017; Zwart *et al.*, 2017)³.

Our data contains very precise information on intensity (hours) of care provided as well a number of mental health and wellbeing measures, and the CCHA can be captured in the British

² According to the Office of National Statistics (2002), a person receiving personal home care in England in 2001, received an average of 7.6 hours/week at a cost of $\pounds 12$ /hour.

³ When different European countries are compared, the effects happen to be especially larger in South-Europe (Brenna and Novi, 2016).

Household Panel Survey (BHPS). We employ a difference in differences (DiD) strategy for the period 1996-2008 in the UK which contains detailed information on a number of important covariates that serve the role of controls. The sample size of caregivers is large enough to carry out our analysis, and the samples have been verified with administrative records, which are consistent with estimates that indicate that informal caregivers make up 17% of the Scottish population (National Records of Scotland, 2016).

Our findings suggest that that CCHA increased the caregiver's happiness domains of the General Health Questionnaire (GHQ) in the post-reform period, but only among caregivers providing more than 35 hours of care per week, and the effects were expectedly larger for female and caregivers out of the labour market . The results apply to both coresident and non-coresident caregivers, and are driven by changes in income of caregivers, and are not explained by changes in health, hospital care, employment, leisure satisfaction.

The paper is organized as follows. The next section reports related literature, followed by section three that describes the institutional setting of the Scottish reform. Section four reports the data, section five provides the empirical strategy, section six reports the results, robustness checks and heterogeneity, and a final section concludes and includes policy implications.

2. Wellbeing effects of caregiving

Stress, mental health and life satisfaction. Compared to non-caregivers, caregivers tend to report lower life satisfaction (Hajek and König, 2016) and quality of life (Rafnsson *et al.*, 2017). Caregivers are more likely to suffer from depression and lower quality of life compared to non-caregivers (Papastavrou *et al.*, 2007; Molyneux *et al.*, 2008; Buyck *et al.*, 2011; Brenna and Di Novi, 2016). They are also more likely to consume prescribed medication and health services (Schulz and Martire 2004, Serrano-Aguilar *et al.*, 2006). In particular, the meta-analysis by Vitaliano *et al.* (2003)

found that caregivers take more medications for physical illnesses, have 23% higher levels of stress hormones and 15% lower antibody responses compared to non-caregivers. These findings are economically relevant and sustained over a long period of time, specifically, they increase the risk of hypertension and diabetes and reduce resistance to viruses (Vitaliano *et al.*, 2004).

Caregiver captivity effect. Pearlin *et al.* (1990) pointed out that a prominent source of caregiver stress results from the so-called 'captivity effect', namely the feeling of being forced to care against one's will. Caregiver depression is directly related to the feeling of being trapped in a particular role with no way out and the expectation that the current situation can only get worse (Ducharme *et al.*, 2007). Informal caregiving is particularly detrimental to wellbeing when caregivers perceive a lack of choice in assuming the caregiving role (Schulz *et al.*, 2012). In fact, recent evidence finds that new-onset Medicaid home care was associated with an improvement of caregivers' health by 3.39% with respect to average pre-onset mental health (Unger *et al.*, 2021). If a caregiver's health deteriorates to the point where they can no longer provide care, the careficier may be at risk of being placed in a nursing home, and awareness of such responsability adds further pressure on the caregiver (Sanders and Power, 2009).

Caregiver's physical health. Certain groups of caregivers are more at risk of poor physical health. Caregivers experiencing a higher level of burden of disease, tend to be older (Rinaldi *et al.*, 2005), female (Papastavrou *et al.*, 2007; Campbell *et al.*, 2008) and co-resident with care receivers (Conde-Sala *et al.*, 2010)⁴. In a meta-analysis of 176 studies on physical health indicators, Pinquart and Sorensen (2007) conclude that older age, lower socio-economic status and lower levels of

⁴ Women have traditionally been the main informal caregivers (Eagly and Wood, 1991; Finley, 1989), have shown greater commitment to caregiving than men (Pavalko and Woodbury, 2000) and have endured greater deterioration in their wellbeing (Pinquart and Sörensen, 2006; Yee & Schulz, 2000). Nevertheless, some studies show some signs of change in the gender gap, resulting from women's entry into the labour market and the effect of equality policies (Glauber, 2017; Langner and Furstenberg, 2020.

informal support are associated with poorer health. Furthermore, higher levels of caregiver behavioural problems are more consistently related to poorer caregiver health, and specifically, overburden is a common mechanism (Orfila et al., 2018). Older individuals and those belonging to lower socio-economic status tend to report poorer health compared to people of higher socio-economic status (Jivraj and Nazroo, 2014), which according to the model of caregiver burden (Pearlin *et al.*, 1990) could make the former more vulnerable to the well-being effects of being a caregiver (Saito *et al.*, 2018; Tough *et al.*, 2020).

Spousal caregivers. Several studies have reported that spousal caregivers experience a higher level of stress compared to other caregivers (Rinaldi et al. 2005; Andrén and Elmstahl 2008). Pinquart and Sorenson (2011) find that spousal caregivers report more depressive symptoms. Caregivers of elderly spouses tend to be older, and may have physical limitations that add to the burden of caring for their spouse (AARP Public Policy Institute, 2013, Pearlin *et al.*, 1990; Snyder, 2000). Social isolation is another problem faced by caregivers (Aneshensel *et al.*, 1993) and there is a positive and significant association between social isolation and caregiver burnout (Akkus, 2011).

Caregiving subsidies and supports. Vulnerable caregivers are at greater risk of caregiver strain when they do not benefit from supports and subsidies services (Sussman and Regehr 2009). However, the caregiver's burden can be alleviated with support (economic or in-kind). Studies of caregivers caring for family members with serious or life-threatening illnesses found that, when caregivers received information related to the progression of the illness, the level of depression considerably declines (Emanuel *et al.*, 2000; McDonagh, *et al.*, 2004). Van den Berg (2006) documents that a cash benefit (€283 on average) paid to a sample of caregivers, reduces caregivers' stress and increases self-reported wellbeing. Similarly, Van den Broek and Grundy (2018) show that a reduction in the availability of home care in Denmark, increases carers' mental health.

Consistently, Vandepitte et al. (2016) conducted a systematic review and concluded that day care services are effective in decreasing caregiver burden. Hence, both subsidies, as well as services and supports, may improve the wellbeing of caregivers' when they experience financial hardship (Amegbor *et al.*, 2021) or their perceived financial burden (Rajapakshe *et al.*, 2018). In addition, subsidies can improve caregivers' esteem as their work becomes more visible to society (Ma *et al.*, 2018), and influences their sense of control over one's own life (Bjørkløf *et al.*, 2016), their participation in leisure activities (Jeong and Park, 2020), as well as social contact, hence reducing loneliness feelings (Wang *et al.*, 2017).

3. The Scottish Reform

Unlike the rest of the UK, Scotland reformed the funding of personal care in 2001 by introducing 'free' personal care (FPC), which meant that all personal charges were abolished, although charges continued for non-personal care expenses. That is, charges for care at home were removed, and a flat-rate subsidy for personal care (as well as for nursing care) to people in care homes was set (Glendinning *et al.*, 2004; Bell and Bowes, 2006 and 2012).

One of the features of the Scottish reform was its swiftness. Scotland formally incepted public subsidisation of LTC in the Community Care and Health Act on a tight time scale (Dickinson *et al*, 2007). Such reform replaced the pre-existing model, still in place in the rest of the UK, of means-tested care whereby local authorities support only individuals whose wealth does not exceed 23,000 pounds. Elderly people in need can only expect to receive a universal attendance allowance (AA). In contrast, under the Community Care and Health (Scotland) Act, people aged 65 years and older are entitled to a flat rate payment of £169 per week, and those who receive care in a nursing home receive an additional £77 per week (as of April 2014).

Additional funds were made available to local authorities on an annual recurrent basis to pay for FPC. Evidence on the Scottish FPC reform to date suggests that costs did not spiral out of control, and that it has overall reduced use of care homes, people on modest incomes benefted the most (Bell and Bowes, 2006 and 2012). The amount spent on care for older people accounted for around 0.2% of Scottish GDP, and the additional costs of providing free personal care for the elderly increased this amount by around 10% after the reform (Bell and Bowes, 2006 and 2012). In contrast, public expenditure projections of LTC estimate expenditure to increase to 1.20% of GDP in 2051 under current funding arrangements, and around 1.45% of GDP in 2051 under a policy of free personal care (Wittenberg *et al.*, 2004). Hence, one can conclude that projections using aggregate macro-simulation analysis rely on a number of assumptions that exaggerate the costs of FPC, rather than on real experimental evidence of FPC.

The welfare effects of FPC are still being quantified. The introduction of the FPC program was mainly politically driven, and linked to the political agenda of the Scottish Labour government (Dickinson *et al.*, 2007). Therefore, the introduction of the program was largely unanticipated, which makes it suitable to undertake an empirical program evaluation analysis.

Nonetheless, the effects on caregiving arrangements are still contentious. Although Bell and Bowes (2006) do not identify any evidence of short term effects on informal caregivers, Kalsberg-Scaffer (2015), drawing on a longer sample, finds suggestive evidence that the introduction of free LTC in Scotland *increased the probability of women supplying informal care by around 6pp*. Hence, we can conclude that the evidence on the impact of FPC caregiving is mixed. However, all points out that the introduction of FPC sharply increased the demand for home-help by 69% between 2002-2010, which was compensated by an increase in the charges for non-personal care, and a subsequent increase in the intensity of care from an average of 6.9 to 7.6 hours/week (Bell and Bowes, 2012).

So far previous studies have not examined the effects on caregivers, and especially, individuals who were caregivers at baseline.

4. The Data

The British Household Panel Survey began in 1991 and is a multi-purpose study whose unique value resides in the fact that it follows the same representative sample of individuals over a period of years. It is household-based, interviewing every adult member of sampled households and contains sufficient cases for meaningful analysis of certain groups such as the elderly, which is the main purpose of this study. The wave 1 panel consists of some 5,500 households and 10,300 individuals drawn from 250 areas of Great Britain. Additional samples of 1,500 households in Scotland and Wales were added to the main sample in 1999, and in 2001 a sample of 2,000 households was added in Northern Ireland, making the panel suitable for UK-wide research. This paper uses the BHPS, a longitudinal study with a common structure for all regions of the UK and a boosted sample for Scotland. The data contains records on mental health indicators, the 12-item version of the General Health Questionnaire (GHQ) developed by Goldberg and Williams (1988).

Our sample employs the General Health Questionnaire (GHQ-12) which is a twelve-item questionnaire that is used to detect psychiatric disorders and is a consistent and reliable instrument when used in the general population (Pevalin, 2000)⁵. Table A1 shows the descriptive statistics for the Scottish sample. This sample is composed of individuals who have provided informal care either

⁵ The scale asks whether the respondent has experienced the following symptoms or behaviors in the last few weeks: 'able to concentrate', 'lost much sleep over worry', 'playing useful part in things', ' capable of making decisions', 'constantly under strain, 'could not overcome difficulties', 'enjoy normal activities', 'been able to face up problems', ' feeling unhappy or depressed', 'losing confidence in oneself', 'thinking of self as a worthless person', 'feeling reasonably happy, all things considered'. Since we are interested in a wider concept of happiness, we focused on the most general domain, i.e. "feeling reasonably happy, all things considered". For the purpose of the analysis, we have reverted the score of the four-level variable, so that a higher score would represent a more positive feeling (i.e. 1="much less", 2="less so", 3="same as usual", 4="more than usual").

at baseline (from 1996 until 2003) or at follow-up (from 2003 until 2008). This choice makes sure that we are able to control both, for people who were caring at baseline and at follow-up, or for allowing the carers composition to change through time. Furthermore, as the number of hours of care provided by an informal caregiver is more reliable when the caregiver is not co-living with the caredfor person, we focus on households with not co-habiting children⁶.

Our treatment refers to individuals living in Scotland after the introduction of FPC, and our control group is composed of respondents living in the rest of the UK. This assumption has been used in field literature (Karlsberg-Schaffer, 2015), which states that carers from both groups were exposed to the same social care funding system before the FPC reform. In our empirical strategy we separate the effect of caregiving at baseline, which allows us to distinguish the effect of selection into caregiving from a change in caregiving intensity among those who were supplying care at baseline.

Looking at Table A1, the two groups seem similar for most of the main characteristics, including age, gender, monthly income and caring effort. There are some differences, although they do not look dramatic. For instance, the Scottish sample shows a lower presence of individuals with at least a degree, and a lower proportion of retired individuals. Notably, the proportion of individuals providing care in Scotland seems to have declined after the FPC reform for all intensities of care apart from the highest (50+ hours per week).

5. Empirical Strategy

Our empirical strategy combines an event study with a differences-in-differences (DiD) approach examining the effect of the reform on Caregivers outcomes.

4.1 Event study

⁶ Following McGarry (1999), co-resident children are excluded, as they may give and receive transfers in kind, which may lead to measurement errors in both the dependent and independent variables.

To analyze how the outcome of interest evolved after the introduction of subsidised LTC in Scotland, we use a flexible event-study design following equation (1).

$$Y_{irt} = \beta_0 FPC_{irt} + \sum_{k=-6}^{k=-1} \beta_{pre}^k \, \mathbf{1} [D_{it} = k] \cdot FPC_{ict} + \sum_{k=0}^{k=6} \beta_{post}^k \, \mathbf{1} [D_{it} = k] \cdot FPC_{irt} + \beta_2 X_{irt} + \vartheta_t + \tau_i + \varepsilon_{irt} \tag{1}$$

where Y_{irt} is the subjective wellbeing indicator, FPC_i is a binary variable that takes the value 1 if the individual *i* living in region *r* at time *t* is beneficiary of the FPC program $1[D_{it} = .]$ is a binary variable that takes the value 1 if there have elapsed *k* terms between the time of the interview and the introduction of the FPC. The term k=0 corresponds to 2002, when the policy was implemented for the first time. We estimate 6 years before FPC (1996-2001) and 6 years after FPC (2003-2008). X_{irt} denotes a set of controls (gender, age, marital status, having non-cohabiting children, education level and monthly income), τ_i are individual fixed effects, ϑ_t are time fixed effects and ε_{irt} is an individual-specific error term.

The parameters of interest, β_{pre}^k and β_{post}^k , corresponds to the effect of the FPC relative to year 2002. This specification allows to test for differences in effects by length of time of exposure and helps to provide a more detailed picture of the relationship between the outcome variables the introduction of the FPC. Additionally, it gives the opportunity to test the validity of the difference-in-difference empirical design. If treated and control individuals had similar trends before policy adoption, and only diverged after the implementation of the FPC, this constitutes strong evidence that such changes were caused by the reform rather than an unobservable factor. In this case, we would obtain that β_{pre}^k are indistinguishable from zero.

4.2 Difference in differences

We draw on a differences-in-differences strategy (DiD) where the treatment refers to exposure of FPC in Scotland (after July 2002). Specifically, we are interested in the effect of the reform on a caregivers wellbeing (Y_{irt}) once we account for a set of relevant controls (X_{ict})⁷. To identify a causal effect, we follow a classical strategy as follows:

$$Y_{irt} = \gamma_0 + \gamma_1 FPC_{irt} + \gamma_2 POST_t + \gamma_3 POST_t \cdot FPC_{irt} + \gamma_4 X_{ict} + \mu_t + \epsilon_{it}$$
(2)

where FPC_{irt} is a binary variable that takes the value 1 if the individual *i* living in region *r* (Scotland or rest of UK) at time *t* is beneficiary of the FPC program (see Table A3 for the evolution of home care in Scotland), $POST_t$ is a binary variable that takes the value 1 for the post-reform period, μ_t are time fixed effects and ϵ_{it} is an individual-specific error term. We are interested in γ_3 , which refers to the changes in the number of outcomes resulting from the introduction of LTC subsidisation over and above the effect of time trends. We can measure the subjective wellbeing of the caregiver and the number of hours of caregiving, and we cluster at the UK county level. We use the two-step procedure proposed by Donald and Lang (2007) to obtain standard errors that do not affect the validity of our results⁸. We report baseline results and a number of robustness checks to make sure that the effect of the reform is robust and does not pick up other potential confounding effects.

Our strategy takes a number of considerations into account. FPC was implemented after June 2002, and hence we can identify the effect by comparing the wave before and after for those that

⁷ Such controsl include gender, age, marital status, having non-cohabiting children, education level and monthly income.
⁸ Donald and Lang (2007) argue that, when the number of regions (clusters) is small in a DiD setting, applying standard asymptotics implies that the significance of the t-statistics is overstated. In order to address this issue, we use the two-step procedure proposed by them which effectively treats the number of region-years as the number of observations. We have 18 regions: Inner London, Outer London. Rest of South East, South West, East Anglia, East Midlands, West Midlands Conurbation, Rest of West Midlands, Greater Manchester, Mereyside, Rest of North West, South Yorkshire, West Yorkshire, Rest of Yorkshire and Humberside, Tyne and Wear, Rest of North England, Wales and Scotland.

would qualify to receive care based on a needs test. However, the effect of the reforms might be nonlinear. In addition, the effects might be different between childless individuals and individuals with children. The latter is particularly important in the presence of 'bequest motives'⁹.

We should acknowledge two potential limitations of our strategy. One refers to the relatively small sample of size of caregivers which varies by specification and hence might reduce the statistical power of our estimates. Table A1 of the Appendix describes the different covariates employed and Table A2 describes the number of observations by age groups for self-reported wellbeing. When we examine the subsample of Scotland, we observe a reasonably large number of observations for 'home help receipt' (Table A3). A second limitation refers to the institutionalized population at baseline included in the dataset, which have been eliminated from the estimates¹⁰.

In estimating the DiD model we should acknowledge that although OLS estimates are not designed to handle ordinal outcome variables their use for DiD model estimation is justified for several reasons. First, Ai and Norton (2003) argue that the interaction effect should be calculated as the double difference of the predicted probabilities, while Puhani (2012) advocates reporting the marginal effect of the interaction term. The difference arises because in a non-linear model the double difference is in general different from zero even when the coefficient of the interaction term is zero, and the discrepancy becomes larger when the probabilities are close to 0 or 1. However, if the distance between the response categories is equal, the linear approximation is used.Second, nonlinear models violate the common trend assumption of the DiD model (Lechner, 2010). For this

⁹ According to the exchange motivation for bequests, theoretical literature on bequests argues that parents reward children who provide informal care and attention with a larger bequest Bernheim et al., 1984).

¹⁰ During the period of analysis, 175 individuals moved from their private home into sheltered accommodation (0.45% of total sample).

reason, its is a common practive to estimate linear models for such ordinal data by applying the assumptions of the linear case to the latent index of the ordinal outcome variable (Puhani 2012).

Third, it is notable that if the intervals between the different values of the latent variable are quite similar, (e.g., that they are uniformly distributed across the true (unobserved) latent variable), then the latent variable can be estimated in a linear fashion way. Just as in the linear regression model an F-test is used to test the null hypothesis that all coefficients of the model except the constant term are zero, the counterpart in the model with ordered dependent variable would be the likelihood ratio test against the null hypothesis that the model contains only a constant term and threshold parameters. Therefore, we estimate two ordered logit models: one model that only includes a constant and one that includes all explanatory variables. Both specifications return similar differences between threshold parameters (results available upon request).

The linear specifications can be considered as a special case of a smoothness restriction in which we impose that the differences in trends are exactly linear11. Rambachan and Roth (2019) recommend performing a sensitivity analysis with respect to the allowable degree of non-linearity in the differential trends. Following this framework, we estimate the year-by-year coefficient and the variance-covariance matrix to exclude the effect of the pre-treatment trend and afterwards extrapolate to the post-treatment period. We have estimated the year-by-year coefficient and confidence intervals at different values of the Rambachan and Roth parameter, which are suggestive of the degree of deviation from the previous trend. The estimated coefficient is positive with a 95% confidence interval for all exposure years, even under the assumption of non-linear trends. This result indicates

¹¹ Pre-trends are informative about what would have happened under the counterfactual, hence a sensitivity analysis is conducted in which confidence sets are reported under different restrictions on the set of possible violations of the parallel trends assumption (Rambachan and Roth, 2019).

that, although the pre-treatment trend might be different, the effect of FPC on caregivers' wellbeing significant after the treatment (results available upon request).

6. Results

5.1 Event study results

Figure 1 shows the results of the event-study for caregivers as a whole (left column) and only for caregivers at baseline (right column). The corresponding coefficients and standard deviations are shown on Table B1. In 2002 there is an increase in the level of happiness of 16.32pp for the whole sample, 24.77pp for women, 23.70 pp for non-active and 28.55 for the bottom income quintile¹². Importantly, there is no significant effect in the year prior to the introduction of FPC. These significant and positive effects are sustained for all subsequent years after the reform, reaching 29.36pp for women and 32.15pp for the non-active in 2007. The effects for the sample of caregivers at baseline are stronger. The overall level of wellbeing increased by 26.21pp in 2002, i.e. 61% higher for all caregivers as a whole. For women, the effect for caregivers at baseline is 122% higher than for all female caregivers.

Figure 2 and Table B2 show the results of the event-study by hours of care provided. estimates are reported for all caregivers (left column) and only for caregivers at baseline (right column). No significant effect is observed for any year for carers who spend less than 10 hours/week, at least 10 hours/week or at least 20 hours/week. Significant effects are observed for the other three categories. In 2002 there was an increase in the level of happiness of 33.1 for C35, 26.6pp for C50 and 26.3pp for C100. Compared to the previous year, this represents an increase of 178.15%, 48.60% and

¹² Following the literature review, on the profile of carers whose level of well-being is most affected by being a carer, the analysis is presented for the total sample and also for the sub-samples of women, non-active (retired + unemployed) and people belonging to the lowest income bracket.

126.72%, respectively. Such effects remain in successive years, and become even stronger for the sub-sample of caregivers at baseline.

[Insert Figures 1 and 2 and Tables B1 and B2 about here]

5.2 Trends

Figure 3 reports evidence of the existing trends for our measure of subjective wellbeing (GHQ-12, "general happiness" item). We focus on the caregiver population in Scotland for the treatment group, whilst the control group refers to the caregivier population in the rest of the UK, where FPC was not implemented. Figure 3 reports evidence of parallel trends that vary by intensity of care.

[Insert Figure 3 about here]

Figures 4 to 6 report the trends in wellbeing measured by GHQ of caregivers (specifically, its "general happiness" domain) based on the total hours of care provided overall and specifically by women (most likely to be caregiver), the non-active population, alongside lower income individuals¹³. The general picture that emerges in Figure 4, is that pre-trends seem to be fairly parallel and do not show significant differences between Scotland and the rest of the UK. However, trends seem to show a *different pattern in the period before the reform among those individuals providing at least 35 hours of care weekly*. In Figure 5 we focus on the non-active population alone, and we find a similar picture as in Figure 4, with the treatment and the control group being closer than in the earlier case. In contrast, the trends in Figure 6 referring to the lowest income quintile population, seem to differ in the period after the reform for the caregivers providing 35 weekly hours of care or

¹³ The graphical analysis has been completed alongside a test of differences between treated individuals vs. non-treated during the pre-reform period.

more. Hence, we can conclude that, as expected, low income earners are more likely to be affected by the reform.

[Insert Figures 4-6 about here]

To further document the hypothesis of common pre-reform period, we regress the outcome variable on the treatment variable and an interaction term of a continuous time variable and an indicator for the treatment variable. If parallel trend holds, we expect the term of the interaction to be statistically insignificant. Consistently, none of the estimated coefficients are significant¹⁴.

5.3 Difference-in-differences estimates

5.3.1 Effects on caregivers at baseline (providing at least 10 hours of care)

In order to make sure that the effects we find account for selection into caregiving, we report a first set of estimates where include all carers who were caring for at least 10 hours both at baseline and at the follow-up. The main DiD parameter, namely the effect fo Scotland after 2002 (panel A) is estimated using a series of dummies that identify carers who were caring for a number of weekly hours varying from 10 hours up to over 100 at baseline and were also caring at the follow-up years (these specifications are identified in the tables as C10, C20, C35, C50 and C100, depending on the number of hours cared at baseline). All specifications control for gender, age, marital status, having non-cohabiting children, education level, monthly income, and a polynomial time trend of the second order. Some of the specifications also control for the actual number of hours cared for (panel B), using the categorical variable available within the BHPS data (10-19 hours, 20-34 hours, 35-49 hours, 50-99 hours and 100+ hours). We ran these estimations for the sample of women with and without

¹⁴ Coefficient and standard deviation for each pre-trend regression (p-value between parenthesis): All sample 0.0318 (0.1269); Women: 0.1489 (0.0992); Non-active: 0.095 (0.1202); Lowest income quintile:0.0017 (0.1262)

ontrols for care hours (panel C and D), the non-active population sample (including retired and unemployed in Panel E and F) and the sample of lower income repsondents (panels G and H). The number of observations and units by treatment group are available in the Appendix in Table A4.

Table 1 reports the effect FPC measured as the effect of Scotland interacted with the period post 2002. Estimates point to an average 10-11p increase in caregivers happiness for the overall sample for carers that at least provide 50 hours of care a week (C50 and C100 samples) and the estimates do not vary significantly significantly when we control for care hours provided. Consistently with the assumption that women do bear most of the caregiving responsability, we find that the effect of FPC is stronger among the female caregivers (we estimate a happiness increase of 13pp (16pp) without (after) controlling for care hours provided). Such estimates suggest evidence of average happiness improvements of 2.2% and 5.7% depending on the hours of care provided. Similar effects are also found for the non-active population groups providing at least 50 hours of care a week (the effects are estimated to be 17pp), and such effect emerge among those providing 35 hours of care at baseline when we control of hours of care. Finally, given that FPC was a universal benefit, it did not change the caregivers in the lowest income groups as they were likely to benefit from previously means tested care available throughout the United Kingdom among individual with wealth below 23,000£.

[Insert Table 1 about here]

5.3.2 *Effects on caregivers at baseline (excluding the implementation year)*

As a robustness check, we have removed the year 2002 from the analysis, as the information about the reform may have affected the behaviour of carers even before the FPC was implemented in law (see Table 2). These even when we exclude 2002, our stimates confirm the previous findings in Table 1, suggesting that in many instances, effects on general happiness are even stronger. We find an average 10-13pp increase in happiness without controlling by hours of care among those who were providing 35 hours of care or more at baseline (panels A and B). As in the previous results, we find larger effects among women (17pp) both without controlling by hours of care among individuals providing at leat 50 hours of care at baseline, and after controlling for them (21pp in panels C and D), and again, effects are larger among non active individuals (19pp without controlling for hours of care, and 23pp when controlling for them in panel E and F). Finally, no effects are found on lower income groups consistently with a benefit extension that was means tested at baseline.

[Insert Table 2 about here]

We have also re-estimated our models controlling for pre-trends and using an ordered probit specification. Results from these analyses are strongly consistent with our main specification, and detailed results have been included in the appendix (see Table B3 and B4).

5.3.3 *Effects on alternative definitions of 'caregiving'*

Next, we have also estimated a less restrictive version of the model which includes also those carers who were providing any hours of care at any point in time. Results from this specification are provided in Tables 3 and 4. Unlike previous results, estimates in Table 3 are less precise but consistent and suggest that including 2002 rises happiness by 12-14pp among women providing more than 100 hours of care, and 16-21pp among non active caregivers providing more than 50 hours of care a week. Finally, we find some positive, though less precise estimates, among lower income groups that vary with the inclusion of controls for hours of care.

[Insert Table 3 about here]

Next, we have performed a final robustness check in which we exclude observations from the year 2002 in Table 4, and consistently, we document estimates consistent with Table 1, namely perceived happiness increases by 10-11pp among the overall sample, a finding that is robust to controlling for hours of care. Estimates are larger (17-18pp) among women, and especially, among labour non-active populations (20-24pp).

[Insert Table 4 about here]

5.3.4 *Effect of Attendance Allowance Expansion*

One potential explananton for our estimates is that some of such effects are driven by a simultaneous increase in the amount of the attendance allowance (AA), a country-wide cash subsidy¹⁵. However, as reported in Table B5, AA after 2002 did not affect the perceived happiness of caregivers. Estimates suggest no evidence of an effect on both the overall sample and the sample of female caregivers (panels A and C). Neither we find an effect when we control for hours of care (panels B and D). Such results are consistent with the hypothesis that cash subsidies might not influence caregivers wellbeing as much as subsidised supports.

5.3.5 Placebos

To enhance the robustness of our results, we have examined the effect of FPC on an unrelated event such as electoral participation in general level elections, as FPC was a devolved reponsability

¹⁵ The Attendance Allowance is a benefit for people over State Pension age who need help with personal care or supervision because of illness or disability (around $\pounds 60.00$ per week if help needed during day or night; around $\pounds 60.00$ per week if terminally ill or help required day and night).

Consistently, Table B6 reports that, as expected, FPC *does not* modify caregivers participation in a general election.

5.3.6 Mechansims

Table 5 reports the DiD estimates of the FPC on the income, employment participation, health, hospitalisations and leisure satisfaction of caregivers to examine the potential mechanisms underpinning previous results. Income improvements can result from form either further employment, the reduction of paid care or other expenses that would take place in the absence of FPC. Consistebtly, FPC can influence employment which can improve the well-being of caregivers re-evaluate their social identity after FPC (Mueser et al., 1997), as well as due to improved opportunities for leisure activities, both of which can impact the subjective wellbeing of family caregivers (Schüz et al, 2015). Finally, FPC might free time which can result in stress reduction, and hence improve health and reduce the probability of hospitalisations.

Again, we distinguish the estimates by hours of caregiving and by including 2002 or not. Results in panels A and B suggest that FPC entailed an income increase of caregivers of 10-15pp depending on the hours of care provided and the inclusion of the year 2002 in the analysis. These estimates suggest that previous results might be driven by changes in caregivers income. Next, we examine whether such estimates are explained by changes in employment. Except for caregivers providing 20 hours of care, where there is an imprecise increase in employee participation, we find no significant effects on employment participation in panels C and D.

Next, examine the effects on caregivers self-reported health as physical health and hospitalisations care have been found to improve after the provision of supports to caregivers. However, our estimates in panels E, F, G and H do not suggest evidence of any significant effects on health and the probability of hospitalisation. Finally, we examine the effect on leisure satisfaction, and our findings in panels I and J suggest no evidence of either effect on leisure satisfaction. These results suggest that although FPC increases wellbeing by providing some respite and additional income for caregivers, most likely resulting from the reduction in the use of paid care, such well-being effect does not affect their health or their leisure satisfaction, not their labour market participation.

[Insert Table 5 about here]

6. Conclusion

This paper exmines the effects of the expansion of caregiving supports on the caregiver's happiness. We estimate the causal effect of the introduction of free personal care' (FPC) in Scotland on caregivers using an event study and a difference in difference approach. We estimate an average 10-11p increase in caregivers happiness for the overall sample for carers that at least provide 50 hours of care a week, and the estimates do not vary significantly significantly when we control for care hours provided. Consistently with the assumption that women do bear most of the caregiving responsability, we find that the effect of FPC is stronger among the female caregivers. Such estimates suggest evidence of average happiness improvements of 2.2% and 5.7% depending on the hours of care provided. Estimates are consistent when we use ordinal probit estimates. Furthermore, event study results suggest a consistent rise in happiness after the introduction of

23

FPC. The estimates appear to be driven by an upgrade of caregivers' financial conditions as we identify improvement in caregivers income, but no effects on their physical health.

Overall, these results provide us with economically relevant evidence to understand the effects of FPC on caregivers wellbeing. The effects are driven by improvement in the wellbeing of female caregivers, and caregivers that do not participate in the labour market. The mechanisms of the effect include changes in caregivers income which might result from a reduction in paid care. Estimates are robust to placebo tests, overall suggesting that the extension of subsidised care supports can exert important wellbeing effects on caregivers. This is important evidence in light of reforms expanding the subsidy for caregiving supports in the United States.

Table 1. Estimation of the difference in difference model of FPC on caregivers happiness (C10: carers providing at at least 10 hours/week at baseline and follow-up; C20: at least 20 hours/week; C35: at least 35 hours/week; C50: at least 50 hours/week; C100: at least 100 hours/week)

Note: C100 includes only unpaid carers who provided at baseline 100 hours or more of weekly care, C50 those who provided at least 50 hours, C35 those who provided at least 35 hours, C20 those who provided at least 20 hours, C10 those who provided at least 10 hours. At follow-up all the carers

have provided at least 10 hours of care. All models presented in the above table control for: gender, age, marital status, having non-cohabiting children, education level, monthly income, and a polynomial time trend of the second order. Additionally, all treated units reside in Scotland.

Table 2. Estimation of the difference in difference model of FPC on caregivers happiness excluding observations from year 2002 (C10:
carers providing at at least 10 hours/week at baseline and follow-up; C20: at leasth 20 hours/week; C35: at least 35 hours/week; C50: at least
50 hours/week; C100: at least 100 hours/week)

Note: C100 includes only unpaid carers who provided at baseline 100 hours or more of weekly care, C50 those who provided at least 50 hours, C35 those who provided at least 35 hours, C20 those who provided at least 20 hours, C10 those who provided at least 10 hours. At follow-up all the carers have provided at least 1 hour of care. All models presented in the above table control for: gender, age, marital status, having non-cohabiting children, education level, monthly income, and a polynomial time trend of the second order. Additionally, all treated units reside in Scotland.

Table 4. Estimation of the difference in difference model of FPC on caregivers happiness excluding observations from year 2002 (C10:

Note: C100 includes only unpaid carers who provided at baseline 100 hours or more of weekly care, C50 those who provided at least 50 hours, C35 those who provided at least 35 hours, C20 those who provided at least 20 hours, C10 those who provided at least 10 hours. At follow-up all the carers have provided at least 10 hours of care. All models presented in the above table control for: gender, age, marital status, having non-cohabiting children, education level, monthly income, and a polynomial time trend of the second order. Additionally, all treated units reside in Scotland

Note: This figure corresponds to an event study created by regressing the outcome variable for a respondent-by-term-by-year cell on a full set of event time indicators interacted with a binary variable for "treatment" and on a set of control variables. This figure reports the coefficients for event-time. that is, the time path of outcome variables in treated vs. untreated individuals before and after of policy implementation and the 95% confidence intervals with robust standard errors clustered at the region-level.

Note: C100 includes only unpaid carers who provided at baseline 100 hours or more of weekly care, C50 those who provided at least 50 hours, C35 those who provided at least 35 hours, C20 those who provided at least 20 hours, C10 those who provided at least 10 hours. At follow-up all the carers

have provided at least 10 hours of care. All models presented in the above table control for: gender, age, marital status, having non-cohabiting children, education level, monthly income, and a polynomial time trend of the second order. Additionally, all treated units reside in Scotland.
