Inequality, poverty, deprivation and the uneven spread of COVID-19 in Europe

Chiara Burlina^a  and Andrés Rodríguez-Pose^b 

ABSTRACT

COVID-19 is mostly considered to have ravaged places with high levels of inequality and poverty. Yet, in the case of Europe, the evidence for this is limited. In this paper we address this gap in our knowledge by exploring how regional variations in poverty, wealth and interpersonal inequality have shaped COVID-19-related excess mortality. The results show that during the first 18 months of the pandemic there is no link between inequality and poverty, on the one hand, and the lethality of the disease, on the other. The geographical concentration of wealthy people is related to more, not less, excess mortality.

KEYWORDS

COVID-19; pandemic; inequality; poverty; institutions; regions; Europe

HISTORY Received 6 February 2022; in revised form 6 January 2023

1. INTRODUCTION

Since the outbreak of COVID-19 there has been no shortage of research, from different disciplinary perspectives, examining the factors behind the unequal diffusion of the pandemic across countries and regions. The factors attracting the greatest degree of scrutiny include: agglomeration and density (Bailey et al., 2020); variations in the preparation and readiness of health systems to cope with the pandemic (Waitzberg et al., 2022); differences in accessibility (Carteni et al., 2021); environmental conditions and pollution (Nižetić, 2020; Travaglio et al., 2021); the structure of local economies (Ascani et al., 2021); or the quality of national and local institutions (McCann et al., 2021; Rodríguez-Pose & Burlina, 2021). Inequality and poverty have also been identified as key drivers of the uneven geography of COVID-19 (e.g., Blundell et al., 2020; Florida et al., 2021).

Wealthier citizens have been often considered to be more shielded from the incidence of the pandemic. They have a greater capacity to work remotely and thus avoid long public transport commutes. They also generally have more space at home, can isolate easier from other members of their household, if hit by the virus, and, during the heights of lockdowns, could escape to their secondary residences in the countryside, mountains or at the coast.

Most less well-off citizens could not afford such luxuries. They often have essential jobs that require face-to-face interaction and cannot be performed remotely. They rely on public transport commutes to reach the office and are often crammed into small apartments in cities. This means that they have been far more exposed to contagion than their wealthier peers. Particularly in cities, at the height of lockdowns there was a return to situations we thought were confined to medieval and early modern history books: the rich, as medieval kings and princes, abandoned the city, while the poor remained stuck to brave the pandemic. Hence, as the risk of contagion for those at the bottom of the pyramid is far greater, higher levels of poverty, more deprivation and greater inequality have been regarded as facilitators of the spread and incidence of COVID-19 (Patel et al., 2020; Rose et al., 2020).

There is no shortage of evidence that this might be the case. Copious research has established a link between poverty and inequality and the impact of the pandemic (Palomino et al., 2020; Tavares & Betti, 2021). However, the majority of the research reaching these conclusions has centred around individual cities or countries (e.g., Wildman, 2021). Subnational comparative analysis involving a large number of territorial units is scarce. At the time of writing, it mostly remains limited to the United States. Tan et al. (2020), for example, have reported that the

degree of income inequalities within US counties determined territorial differences in the incidence of COVID-19. In the case of Europe, there is to date no similar comparative analysis covering most regions.

However, not all evidence supports the idea that the poor have suffered more from the pandemic. Country-level research has brought to light that many developed countries have been hard hit by the pandemic. The evidence from less developed is far more mixed. Some have suffered greatly from successive waves of COVID-19, but others, especially in Africa and Asia, have weathered the storm relatively unscathed, notwithstanding their weaker health systems and institutions (Adams-Prassi et al., 2020; Ali et al., 2020; Deaton, 2021).

In this paper we assess the extent to which poverty, material deprivation, wealth and interpersonal inequality at a regional level in Europe are related to geographical variations in the impact of COVID-19, proxied by excess mortality, during the first three waves of the pandemic (January 2020–end of June 2021). The analysis is conducted for a total of 228 regions, building an original database using different data sources: Eurostat, EU-SILC, the Luxembourg Income Study (LIS) and the Quality of Government Index. We use different indices to reflect the broad field of interpersonal inequality: the Gini coefficient at the local level, as well as poverty and material deprivation levels and shares of the population in different income groups. We compute the excess death rates relative to the previous five years on a weekly basis from January 2020 to June 2021, as a percentage change. We also control for other possible factors identified by the scholarly literature that may influence the impact of COVID-19.

Our results highlight that, in the case of Europe, in regions with a greater share of poor people or higher levels of material deprivation, the connection between poverty and excess mortality is, in contrast with expectations, mostly negative. There is thus no evidence, across the whole of Europe, that poverty and deprivation at the regional level have influenced geographical differences in the impact of the pandemic. When we consider the share of the regional population in the top quintile or the top 5% of the European income distribution, we find that places with a higher share of wealthy people have had a ‘bad’ pandemic. We also find no link between variations in the levels of regional interpersonal inequality and excess mortality.

The remainder of the paper is structured as follows. Section 2 delves into research connecting interpersonal inequalities and the spread of the pandemic. Section 3 describes the main data and methodology. Section 4 presents the main results. Finally, section 5 concludes and dwells on some potential policy implications and the lessons learned for future crises.

2. INEQUALITIES AND THE PANDEMIC

The geographical spread of COVID-19 is considered to be the consequence of a variety of different factors.

These range for the purely economic, to social, political and environmental (Bailey et al., 2021; McCann et al., 2021; McKibben & Fernando, 2020; Zambrano-Monserate et al., 2020). Among these, substantial attention has been paid to the extent to which income inequalities have affected COVID-19-related differences in mortality (Brodeur et al., 2021). The focus on the link between inequality and the incidence of pandemics is not new. Research analysing previous pandemics has also put the limelight on inequality. The results from this type of research mostly point in the direction that inequalities shape geographical variations in the intensity of COVID-19 and that individuals at the bottom of the income pyramid have been more exposed to contagion throughout the pandemic (Costa Dias et al., 2022; Deaton, 2021; Glover et al., 2020; O’Donoghue et al., 2020; Paul et al., 2021; Wildman, 2021). Oronce et al. (2020) connect interpersonal inequalities – proxied by the Gini index – with COVID-19 cases and deaths during the first four months of the pandemic in the United States. They find that states with a higher Gini index were precisely those with a higher number of COVID-19-related deaths. The presence of disadvantaged population groups has also been associated with a higher incidence of disease. Areas of the United States with an ageing population, large, disadvantaged minorities (mainly African American and/or Hispanic), or a higher share of people below the poverty line have been more affected by the virus (p. 2791).

The reasons for this connection are multiple. Individuals at or below the poverty line or suffering material deprivation usually face worse conditions in their daily lives. First, they are more likely to live in small and overcrowded flats, situated in high-density areas (Aldridge et al., 2021; Clair, 2022; Wheeler et al., 2008). They also have less information (or less access to information) about the illness and its consequences and, on average, tend to perform low-skilled jobs which require, in most of the cases, face-to-face interactions (Alam & Parvin, 2021; Avdiu & Nayyar, 2020; Goldman et al., 2021; Montenegro et al., 2020). Finally, due to their precarious economic conditions, they had limited opportunities to flee the big cities when the pandemic first struck (Davydiuk & Gupta, 2020; Fraiberger et al., 2020). Hence, many individuals at or below the poverty line have been stuck in densely populated cities – which were the initial foci of COVID-19 – throughout the pandemic. They have weathered lockdowns and confinements mostly in cramped accommodation, while, in many cases, continuing to perform their essential duties face to face. Especially in the United States, many people have also had more limited access to healthcare.

By contrast, the better-off have been more sheltered from the virus (Esposito et al., 2021; Schellekens & Sourrouille, 2020; Sibley et al., 2020). Wealthier citizens have bigger houses and live in less cramped conditions and with far greater access to gardens and outdoor open space. They make the bulk of the ranks of white-collar jobs that have been far more easily conducted remotely

than blue-collar and low-skilled service jobs (Belzunegui-Eraso & Erro-Garcés, 2020; Lambert et al., 2020). They are also less likely to use public transport and rely to a greater extent on the car. And, at the outbreak of the pandemic, many of them were capable of leaving the cities for their secondary residences in the countryside, mountains or by the sea. Fleeing the city provided them with greater shelter from contagion (Coven & Gupta, 2020).

Overall, this evidence has been translated into a widespread perception that, in places with a higher concentration of poor and materially deprived people, the impact of the pandemic would have been greater; that the poor have had a worse pandemic (Palomino et al., 2022). By contrast, areas with a high share of people in the top income ranks would have had – everything else being equal – an easier ride. Therefore, inequality should be an important driver for the diffusion of, and for variations in, the incidence of COVID-19.

However, despite the abundance of scientific research focusing on inequality, wealth, poverty and material deprivation and how these factors may have affected the diffusion and incidence of the pandemic, considerable gaps remain in our knowledge. Many of the studies focusing on poverty and inequality are centred around specific cases – often at the local or city level – or, by contrast, are conducted at the national level (Darvas, 2021; Deaton, 2021; Elgar et al., 2020; Hacıoğlu-Hoke et al., 2021; Holst et al., 2021). But there remains a dearth of research centred on how inequality, poverty, material deprivation and wealth affect the diffusion of the pandemic at a wider regional level. Comparative and multiscale cross-regional analysis remain limited. And there is considerable scope for improvement when comparing how inequalities and poverty have shaped geographical variations in the pandemic with the potential sway of other factors, such as density, accessibility, regional wealth, government efficiency, pollution or the readiness of health systems to cope with such an emergency (Rodríguez-Pose & Burlina, 2021).

The reason behind the lack of in-depth, comparative cross-regional analyses is often related to the absence of data on interpersonal inequality. This is particularly a problem at the European level. Until now, in Europe variations in interpersonal inequality across regions have not been adequately mapped. We fill this gap in the existing knowledge by establishing a link between different measures of poverty and wealth and income inequalities, on the one hand, and the geographical variation in the incidence of COVID-19, on the other, across as many regions of Europe as the data allow. This implies answering two different research questions:

- What is the role of poverty, material deprivation, wealth and inequality within regions of Europe in the incidence of the COVID-19 pandemic?
- How do poverty, material deprivation, wealth and inequality compare with other factors that have been highlighted by past research as drivers of variations in the incidence of COVID-19?

Based on the existing scholarly literature on inequalities and the spread of the pandemic, from each research question we derive hypotheses to be tested in the empirical analysis. The first hypothesis is directly related to the first research question and can be divided into three sub-hypotheses, considering poverty, material deprivation, wealth and overall inequality levels across European regions. This hypothesis is formulated as follows:

Hypothesis 1a: A greater share of people at or below the poverty line or suffering from material deprivation in a region will lead to increases in the incidence of COVID-19.

Hypothesis 1b: A greater share of wealthy individuals in a region will lower the incidence of COVID-19.

Hypothesis 1c: Interpersonal inequality will thus be a driver of variations in the incidence of COVID-19 across regions of Europe.

In response to the second research question, we can formulate the following hypothesis:

Hypothesis 2: Interpersonal inequality is, at least, as important a factor explaining variations in the incidence of COVID-19 as other factors that have been previously highlighted by the literature, such as regional wealth, government efficiency, pollution, levels of education, age of the population or the readiness of health systems.

3. DATA DESCRIPTION AND METHODOLOGY

In order to address the questions driving this research and to assess the link between the different measures related to income inequalities and variations in the impact of the COVID-19 pandemic, we put together a unique dataset covering both the incidence of the pandemic – proxied by excess mortality relative to the previous five years – alongside different measures of poverty, wealth and interpersonal inequality. The dataset is complemented by several controls for European regions.

3.1. The dependent variable

Our dependent variable is the incidence of the pandemic. Following a rising number of studies (e.g., Beaney et al., 2020; Davies et al., 2021; Rodríguez-Pose & Burlina, 2021), we use all-purpose excess mortality rates in the previous five years before the outbreak of the pandemic. This variable is preferred to alternatives, such as the number of cases or the number of cases treated in hospital, because it has been measured in a far more consistent and accurate way – the number of COVID-19 cases, for example, has been greatly affected by factors such as the capacity to measure at different times of the pandemic and is prone to political manipulation (Rodríguez-Pose & Burlina, 2021). We cover four periods of the spread of COVID-19: (1) between January 2020 and the end of June 2021;

(2) the first six months of 2020; (3) the second six months of 2020; and (4) the first six months of 2021.

The dependent variable – displayed here for 2020, as an example – is computed according to the following formula:

$$Exc_deaths_{2020} = \frac{deaths_{2020} - deaths_{2019-2015}}{deaths_{2019-2015}} * 100 \quad (1)$$

Excess mortality is calculated as the percentage difference between the number of deaths per week in a given period and the average deaths in the same period during

Table 1. Excess deaths periods.

Period	Start week	End week
2020–21	Week 1, 2020	Week 27, 2021
I semester 2020	Week 1, 2020	Week 27, 2020
II semester 2020	Week 28, 2020	Week 54, 2020
I semester 2021	Week 1, 2021	Week 27, 2021

the period 2015–19, divided by the average number of deaths between 2015 and 2019. Table 1 reports the four different periods considered in the analysis, highlighting both the starting and the ending week.

The geographical incidence of the pandemic has varied significantly both across time and space (Figure 1). Overall, during the first 18 months of the pandemic there were areas of Europe that had a ‘good’ pandemic. In Norway, for example, mortality between January 2020 and the end of June 2021 was lower than the average of the previous five years. Some other European regions in southern and western Greece, southern Italy (Basilicata and Calabria) and Lazio, Aquitaine, Brittany and Limousin in France, or Galicia and Cantabria in Spain witnessed only marginal increases in mortality. By contrast, COVID-19 ravaged through most of Poland, the Czech Republic, parts of Slovakia and Bulgaria. Some Western European regions, including some of the continent’s wealthiest, such as Lombardy and Trentino in Italy,

Madrid and Castile-La Mancha in Spain, or London in the UK, were also prominent foci of the pandemic.

However, the picture of the first 18 months of COVID-19 in Europe hides considerable time variations. Different waves and variants of the virus have affected regions of Europe differently. These differences are represented in Figure 2. The first wave – covering the first six months of 2020, but really hitting Europe between late February and May 2020 (Figure 2a) – caught most of Europe by surprise (Ahmed et al., 2020; Kandel et al., 2020; Liang et al., 2020). The highest incidence took place in Western Europe and, very often, in highly connected and large cities, which acted as the entry points of COVID-19. Some of the largest European agglomerations – Madrid, Milan, London, Paris, Brussels or Stockholm – suffered massively during the first wave. In contrast, the incidence was limited in many rural areas and across most of Central and Eastern Europe, with the exception of parts western of Poland and western Czechia.

The second wave, reported in Figure 2b, took place during the autumn of 2020. It hit Central and Eastern Europe hardest, while the Nordic countries, western France, southern Greece and parts of the UK were relatively spared. All the way from Bulgaria to Lithuania excess mortality surpassed 20% with respect to the same period in the previous five years. Regions along the Alpine Arc from Slovenia to central France and across Austria, Switzerland and northern Italy also saw the incidence of the pandemic soar, as was the case of Wallonia in Belgium, Sardinia in Italy, and regions in northern Spain and northern Portugal.

The final wave covered in the analysis is concerned with the first six months of 2021 and coincided with the launch of mass vaccination across the continent (Figure 2c). This third wave fundamentally affected Central and Eastern European countries. Czechia, Slovakia, Bulgaria and Poland were hit by the spread of COVID-19 with full force. Many regions in France, the Netherlands, Portugal and the UK also had a 'bad' third wave. But, in

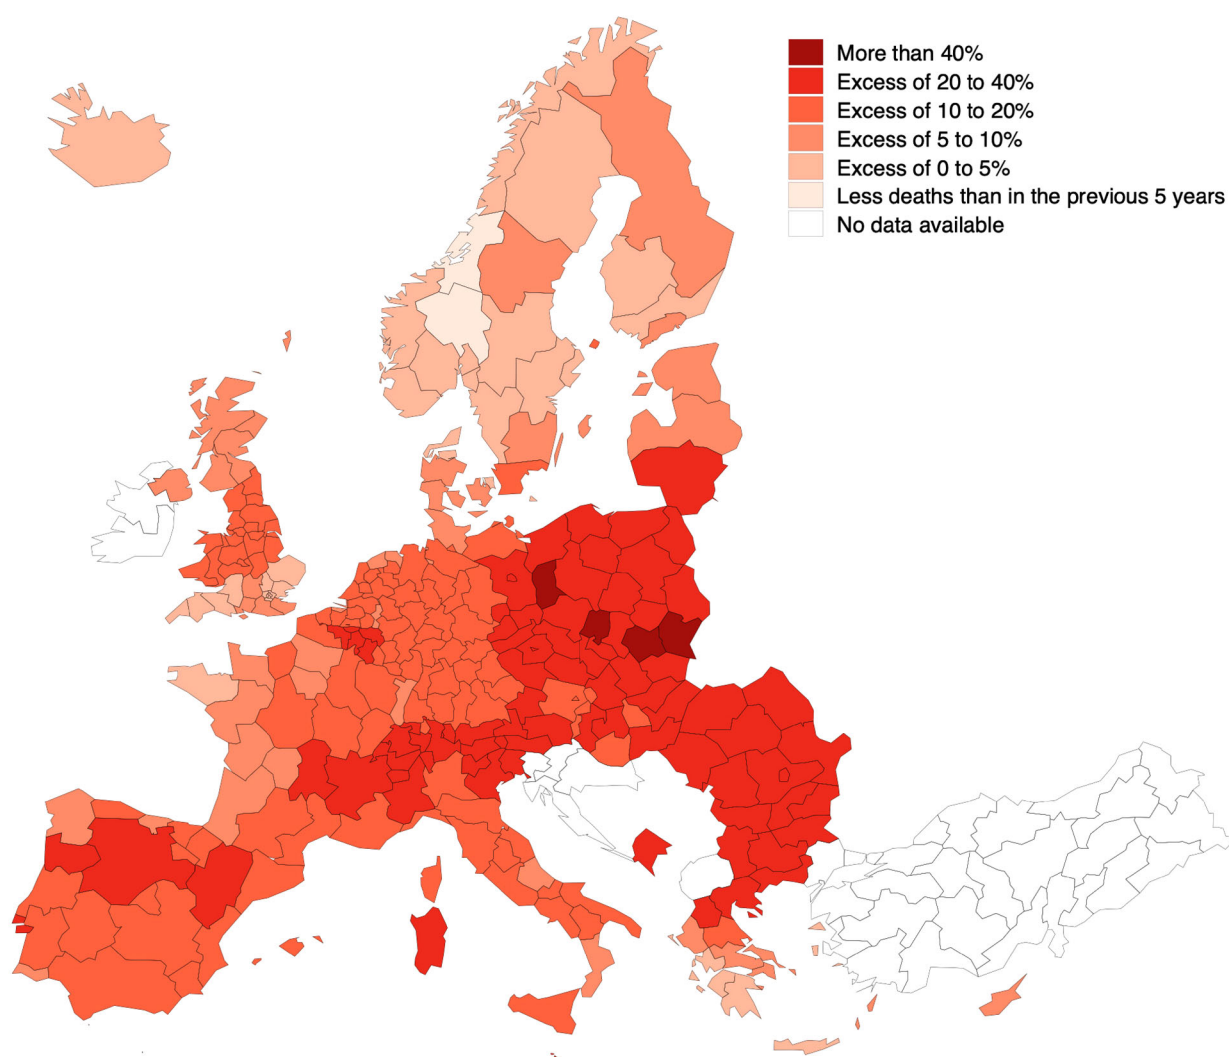

Figure 2b.

general, the incidence of the pandemic was far lower across Western Europe and in particular in the Nordic countries, Belgium, western Switzerland and parts of north-western Spain. In most of these places there was no excess mortality in the first half of 2021.

3.2. The inequality variables

Our main variables of interest relate to different measures of poverty and inequality. We test the connection between poverty, wealth, and income inequalities and geographical variations in the impact of the pandemic using several variables: the overall share of relative poverty and the percentage of people at severe risk of material deprivation in a region; the share of people in the top 20% of the income distribution; the share in the top 5%; and the Gini index, as our proxy for interpersonal inequality within regions.

The relative poverty measure stems from Eurostat's Statistic on Income and Living Conditions (SILC) survey. This survey collects information on age, year of birth, country of birth, living conditions and poverty for European citizens at the NUTS-2 regional level. The relative

poverty index is selected for 2018, except for the UK where, for lack of data, the reference year is 2017.¹

As shown in Figure 3, poverty is highly concentrated in certain regions of Europe. Levels of poverty in the Italian Mezzogiorno, northern and eastern Bulgaria, north-eastern and eastern Romania, and Estonia and Latvia exceeded 30% of the population in 2018. By contrast, in specific regions such as Helsinki in Finland, Central Bohemia in Czechia, Navarra in Spain, or Burgundy and Rhône-Alps in France, less than 10% of the population were below the poverty line.

The index for material deprivation uses EUROSTAT data (Figure 4). It compiles indicators measuring economic strain, durables, housing deprivation and dwelling conditions. The index is frequently used as another proxy for the level of absolute poverty, and takes into account incomes in kind, free or subsidized goods, and self-supply (Łuczak & Kalinowski, 2020; Serafino & Tonkin, 2017).² Material deprivation is higher in the Southern and South-Eastern fringes of Europe and, fundamentally, in eastern Bulgaria and Romania, Campania and Sicily in Italy, and western

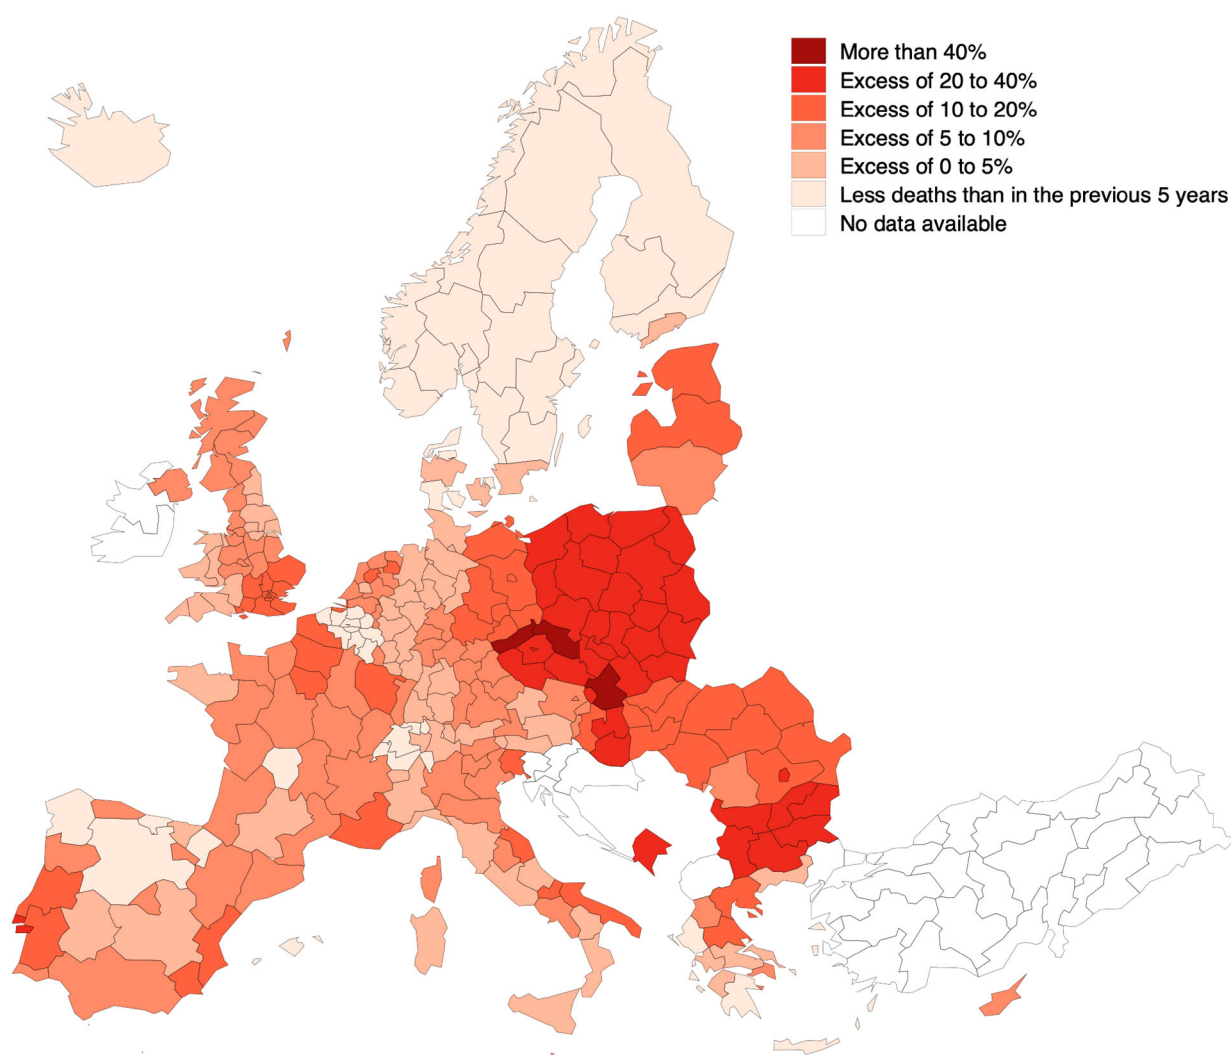

Figure 2c.

Greece. Material deprivation is far lower in the Nordics or the Netherlands.

On the other side of the coin, wealth is equally geographically concentrated.³ But rather than in lagging-behind regions, mostly in large cities. In London, Paris, Madrid, Prague or Helsinki more than 30% of the regional population was in the top quintile in terms of income (Figure 5). The Basque Country belongs in this group as well. More than 20% of the population is in the top quintile of income in Denmark, the north of Italy, the south-east of England and East Anglia, some northern Spanish regions, Lisbon, and certain regions in France. But a non-negligible number of regions in Central and Eastern Europe, from the Baltics to Bulgaria, also belong in this category. By contrast, in Extremadura in Spain and Champagne-Ardenne in France, less than 10% of the population had incomes in the top quintile (Figure 5).

Mapping the population in the top 5% of the income band reveals a pattern that is not that dissimilar from that of the population in the top income quintile (Figure 6). The richest individuals concentrate in the three largest

agglomerations (by population) covered in the analysis: London, Paris and Madrid, precisely cities strongly affected by the outbreak of the pandemic. Concentrations of the population in the top 5% of income band can also be found in some rich regions, such as parts of the south-east of England, the north of Italy, Helsinki, the Balearic Islands, Basque Country and Catalonia in Spain, Alsace and Midi-Pyrénées in France, and in capital cities such as Athens, Budapest, Helsinki, Lisbon, Prague or Sofia. There is an even higher percentage of the population in the top income band in Bucharest and the surrounding region (Figure 6).

By contrast, the north of Finland and Sweden, the north-east of England and Yorkshire, the south of Italy, southern Spain and southern Greece, as well as eastern Hungary, and most of Bulgaria and Romania had the lowest shares of people at the top of the income pyramid (Figure 6).

The last inequality variable is represented by the Gini of disposable income. For this index we rely on two data sources. The first is the SILC survey, which measures this index as the extent to which the distribution of

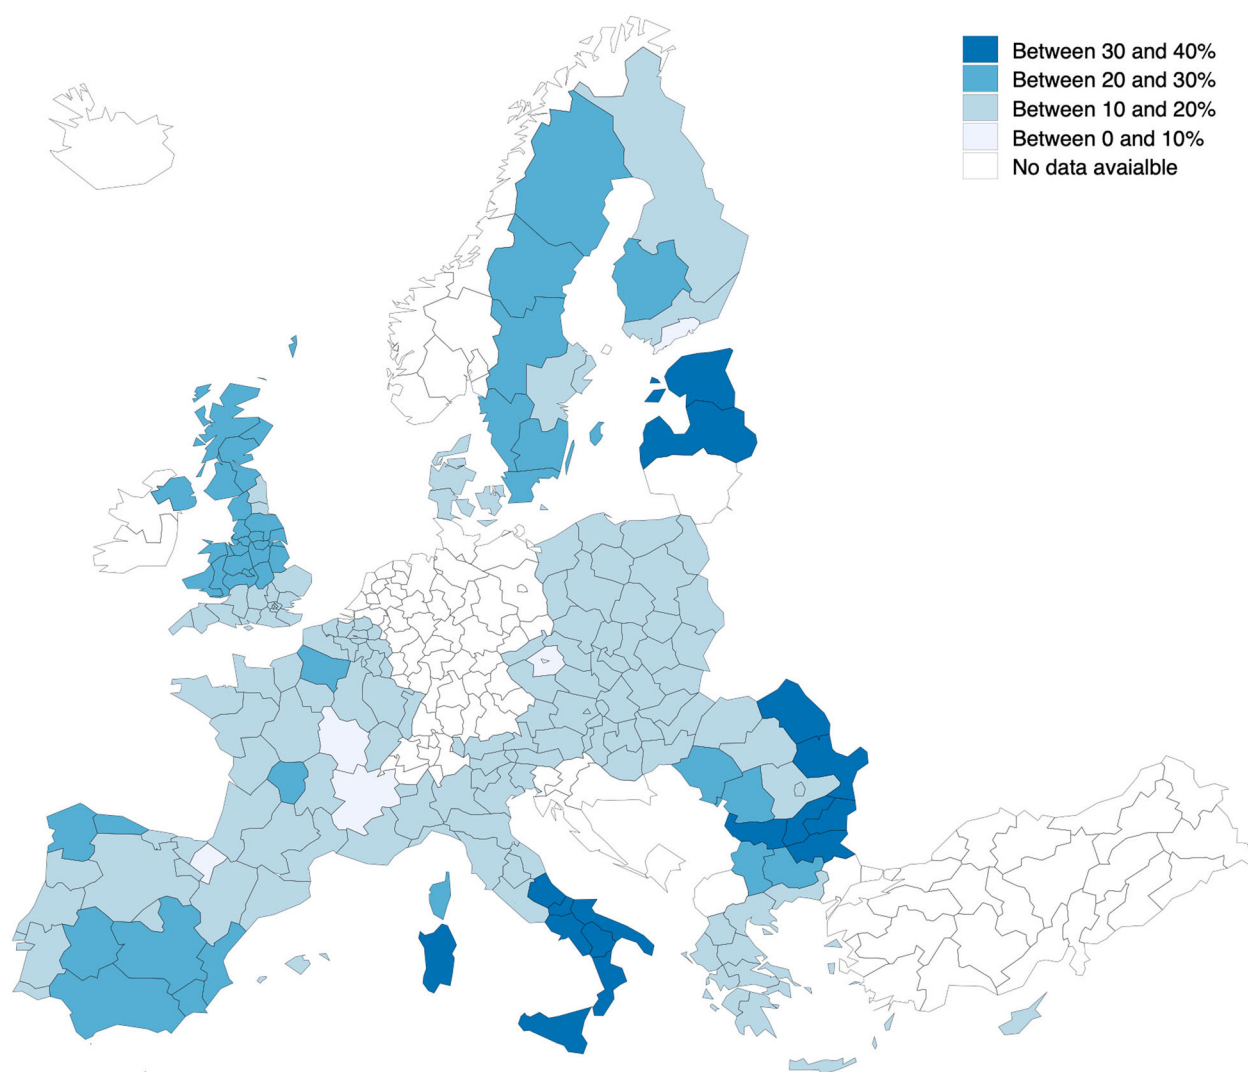

Figure 3. Relative poverty index by region.
Source: Authors' own elaboration.

equivalized disposable income after social transfers deviates from a perfectly equal distribution. The second source is the Luxembourg Income Study (LIS) (Ravallion, 2015), used for German regions in 2016 (the last available year for this country). In both cases, the Gini index is a summary measure of the cumulative share of equivalized income accounted for by the cumulative percentages of the number of individuals. Its value ranges from 0 (complete equality) to 1 (complete inequality). The geographical representation of this variable is reported in Figure 7.

Interpersonal inequalities in Europe are highest in some of the poorest regions of Eastern Europe, including all of Bulgaria, the north-east of Romania and Latvia. Some poorer regions in Western Europe – such as Sardinia or Sicily and, to a lesser extent, most of the south of Italy, the majority of the north and east of the UK, most parts of Spain and the whole of Portugal – also had high internal levels of income polarization. However, interpersonal inequality was also high in the biggest and most dynamic cities, such as London and

Paris and, to a lesser degree, Madrid, Budapest, Warsaw and the relatively prosperous German regions of Bavaria and Hesse (Figure 7). The lowest levels of income inequality were confined to Slovakia, most of the Czechia, Saxony in Germany and regions such as Navarre in Spain, and Champagne-Ardenne, Lower Normandy and Poitou-Charentes in France.

3.3. Control variables

Other factors, such as regional wealth, pollution or accessibility also influence – according to previous scholarly literature – the geographical variations in the incidence of COVID-19. We use different indicators to control for these factors. First, we resort to gross domestic product (GDP) per capita in 2018 as our proxy for regional wealth. Density is measured by the population per km² in 2018. The role of institutions is proxied by the national government effectiveness in 2018, which captures the quality of public and civil services and the degree of its independence from political pressure (Kaufmann & Kraay, 2020). Our

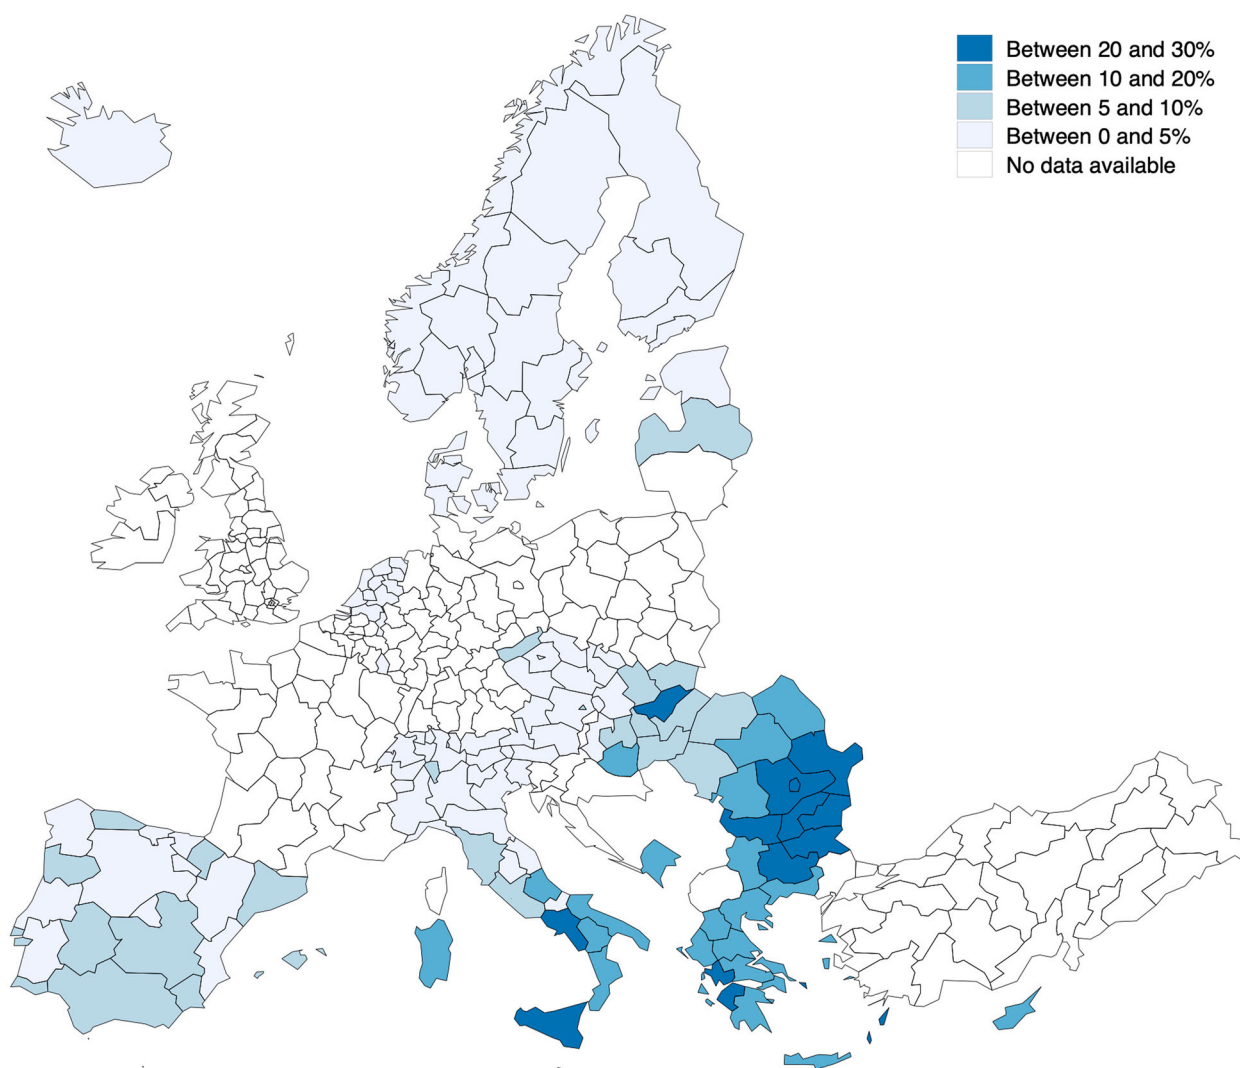

Figure 4. Severe material deprivation index by region.
Source: Authors' own elaboration.

proxy for environmental conditions is exposure to air pollution by particulate matter ($PM_{2.5}$) at regional level in 2019. The readiness of different health systems to fight the pandemic are measured by the number of per capita hospital beds in the same year. We also control for the education of the population and its median age. Finally, we introduce connectivity, a factor deemed to have severely affected the spread of the pandemic (Bourdin et al., 2021; Rodríguez-Pose & Burlina, 2021). We measure connectivity both by air and road, using the number of air passengers arriving in a region in 2018, for the former, and the inverse time-distance weighted population for 2014, for the latter.

The description, source and summary statistics of the different variables included in the analysis are reported in Table A1 in Appendix A in the supplemental data online.

3.4. Methodology

The empirical analysis is based on a set of ordinary least squares (OLS) regressions covering the period under observation. The general model adopts the

following form:

$$Y_i = \beta_0 + \beta_1 \text{Income Inequalities}_i + \beta_2 X_i + \varepsilon_i \quad (2)$$

where Y_i represents the excess of mortality rates computed in the four periods presented in Table 1. *Income Inequalities_i* stands for the relative poverty index, the 20% and 5% shares of people in the regional income distribution, and the Gini coefficient. Each variable is included in the model successively. Finally, the vector X_i contains the other control variables – GDP per capita, change in national government effectiveness, population density, accessibility (both by air and road), and hospital beds per capita. ε_i is the error term. To correct for error correlation within regions, we cluster the standard errors at the regional level.

4. RESULTS

Table 2 introduces the results when relative poverty is considered as the main variable for income inequalities. Each column reports the four different periods under scrutiny, first introducing relative poverty and GDP per capita,

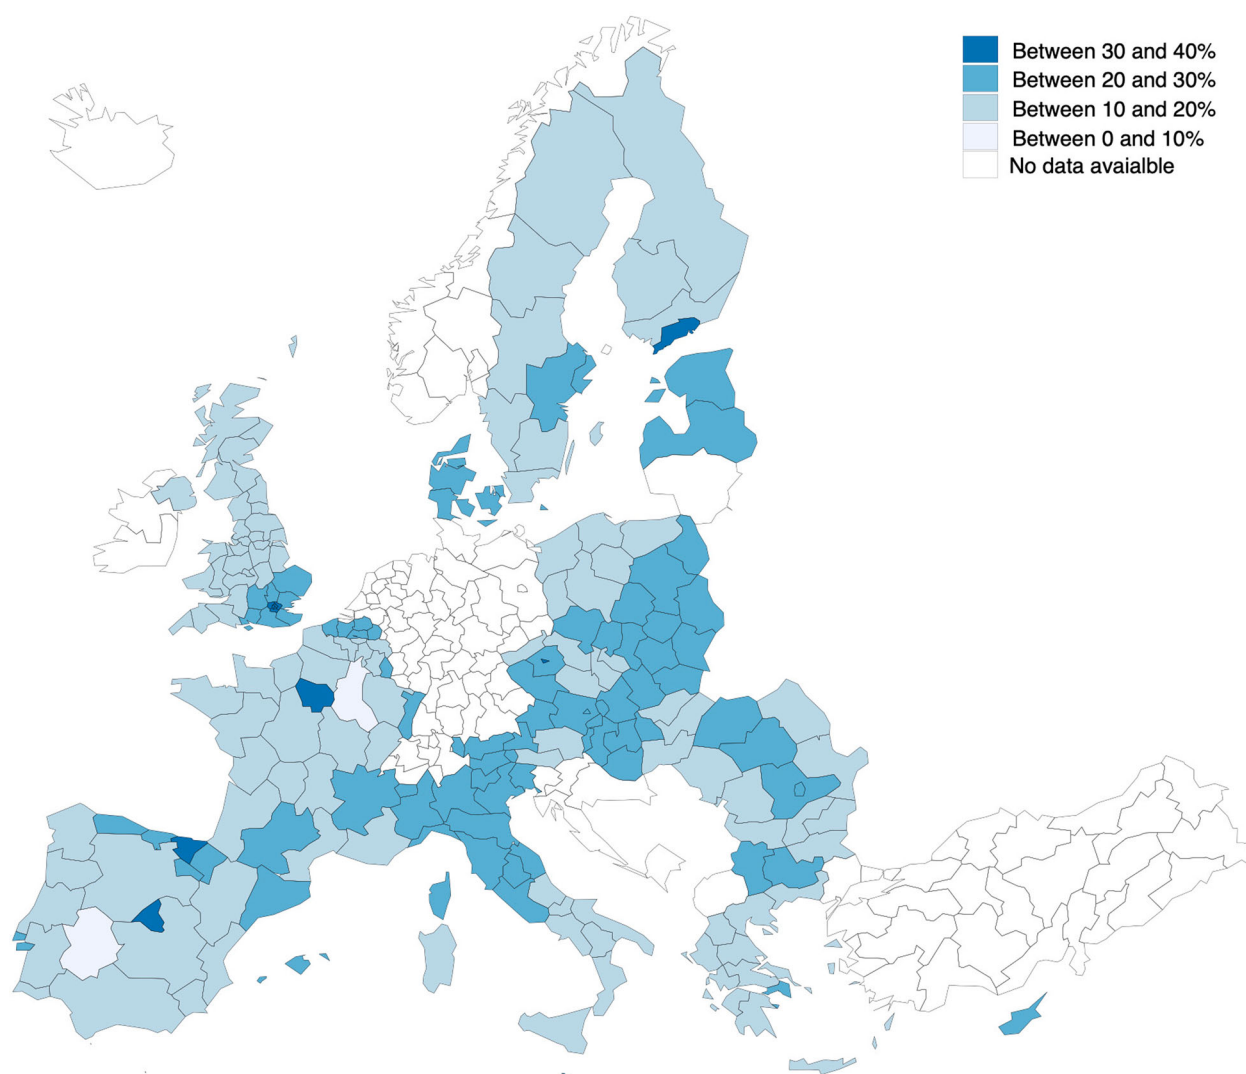

Figure 5. Share of the population in the top 20% of the income distribution by region.
Source: Authors' own elaboration.

second adding to these two variables the other factors that reportedly affect the spread of the pandemic.

According to Hypothesis 1, a concentration of people below the poverty line should have resulted in a greater incidence of COVID-19-related excess mortality. However, there is no evidence in our results of this being the case (Table 2). European regions with a greater share of people at the bottom of the income pyramid have, as a general rule, less – and not more, as expected – excess mortality during the first 18 months of the pandemic and especially in the second and third waves. The coefficient for relative poverty in a region is negative and significant in regressions 1, 5 and 7 of Table 2, when controlling for regional wealth. Once other factors that may have affected variations in the incidence of COVID-19 are inserted in the analysis, the coefficient for relative poverty remains negative, but becomes insignificant (Table 2, regressions 2, 4, 6 and 8). Hence, there is no evidence across European regions that poverty has been a driver of the pandemic. Other factors such as regional wealth, pollution or accessibility by road show a significant and

stronger connection with excess mortality (Rodríguez-Pose & Burlina, 2021). On the whole, poorer, more polluted, more accessible regions and those with a weaker health system have suffered more from the impact of COVID-19 (Table 2). By contrast, regions with a more educated population and with a higher average age, once other factors are controlled for, experienced lower excess mortality. The main exception is the first wave of the pandemic in the first half of 2020, which caught everyone by surprise and trying to understand what befell us (Bourdin et al., 2021). During this wave, wealthier regions with a better health system – often also the entry ports of the pandemic in Europe – experienced higher excess mortality. But, as the pandemic increasingly became endemic, excess mortality receded in regions with stronger health systems and surged elsewhere.

The results hold also when we look at the percentage of people experiencing severe material deprivation in Table 3. The coefficients point to a negative link between the prevalence of material deprivation at a regional level and the incidence of COVID-19-related mortality. The

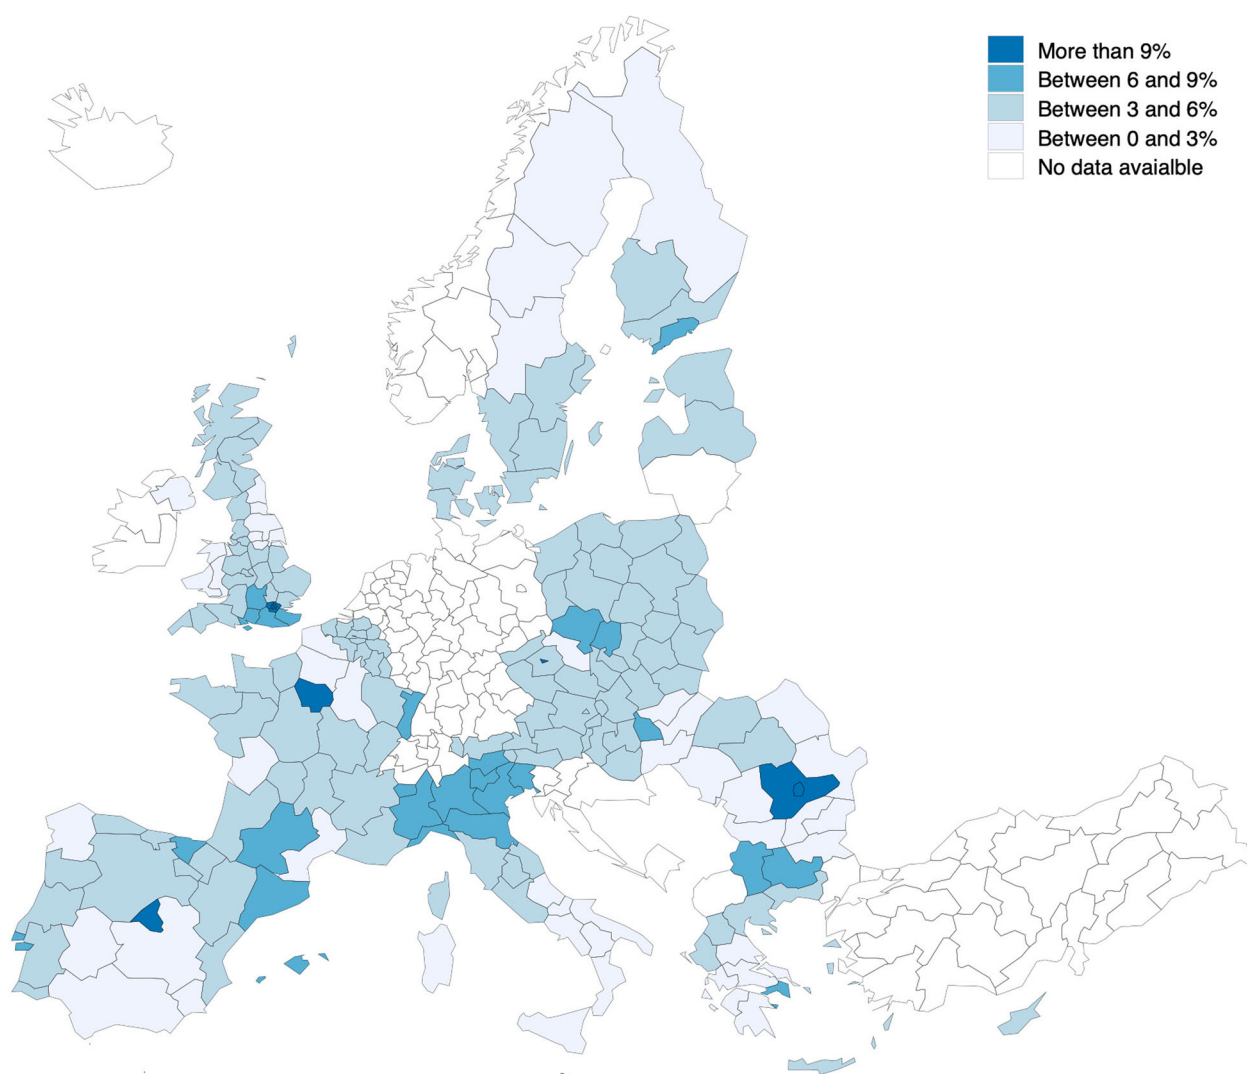

Figure 6. Share of the population in the top 5% of the income distribution by region.
Source: Authors' own elaboration.

coefficient for material deprivation becomes stronger when the other control variables are included in the model, supporting the results of [Table 2](#).

When rather than focusing on those at the bottom of the pyramid, we put the spotlight on those at the top, the results go in the same direction. Having a greater share of individuals in the top income quintile has been connected to higher, not lower excess mortality. This applies for the first 18 months of the process, as well as for every subperiod considered ([Table 4](#)). At a regional level in Europe, we find no evidence that the presence of wealthy individuals in a place reduces the incidence of the pandemic (Deaton, 2021; Han et al., 2020; Islam et al., 2021).

Most other control factors have similar coefficients to those reported in [Table 2](#). More polluted and more accessible places (by road) have been more vulnerable to the pandemic, as have been poorer regions, with the exception of the first wave ([Table 4](#), regression 4) (Valero & Valero-Gil, 2021). These results are confirmed when we consider the share of individuals in the top 5% of the income distribution in [Table 5](#).

To test Hypothesis 1c we introduce in [Table 6](#) the overall measure for income inequalities, proxied by the regional Gini index. The results suggest that interpersonal inequality at a regional level is incapable of explaining geographical variations in the incidence of COVID-19 across Europe. Only in the first wave of the pandemic there seemed to be a positive connection between regional inequality and excess mortality ([Table 6](#), regression 3), but this association disappears completely when the controls are introduced in the regression (regression 4). On the whole, the connection between interpersonal inequality and excess mortality is insignificant ([Table 7](#)).

The results for Europe thus go against most expectations in the scholarly literature on COVID-19. We find no evidence whatsoever to support Hypothesis 1, as regional excess mortality during the first 18 months of the pandemic in Europe is not connected with poverty or inequality levels and, if anything, is linked to the presence of wealthy individuals in a region. Hence, interpersonal inequality in European regions seems to have played a far less important role in variations of the impact of the

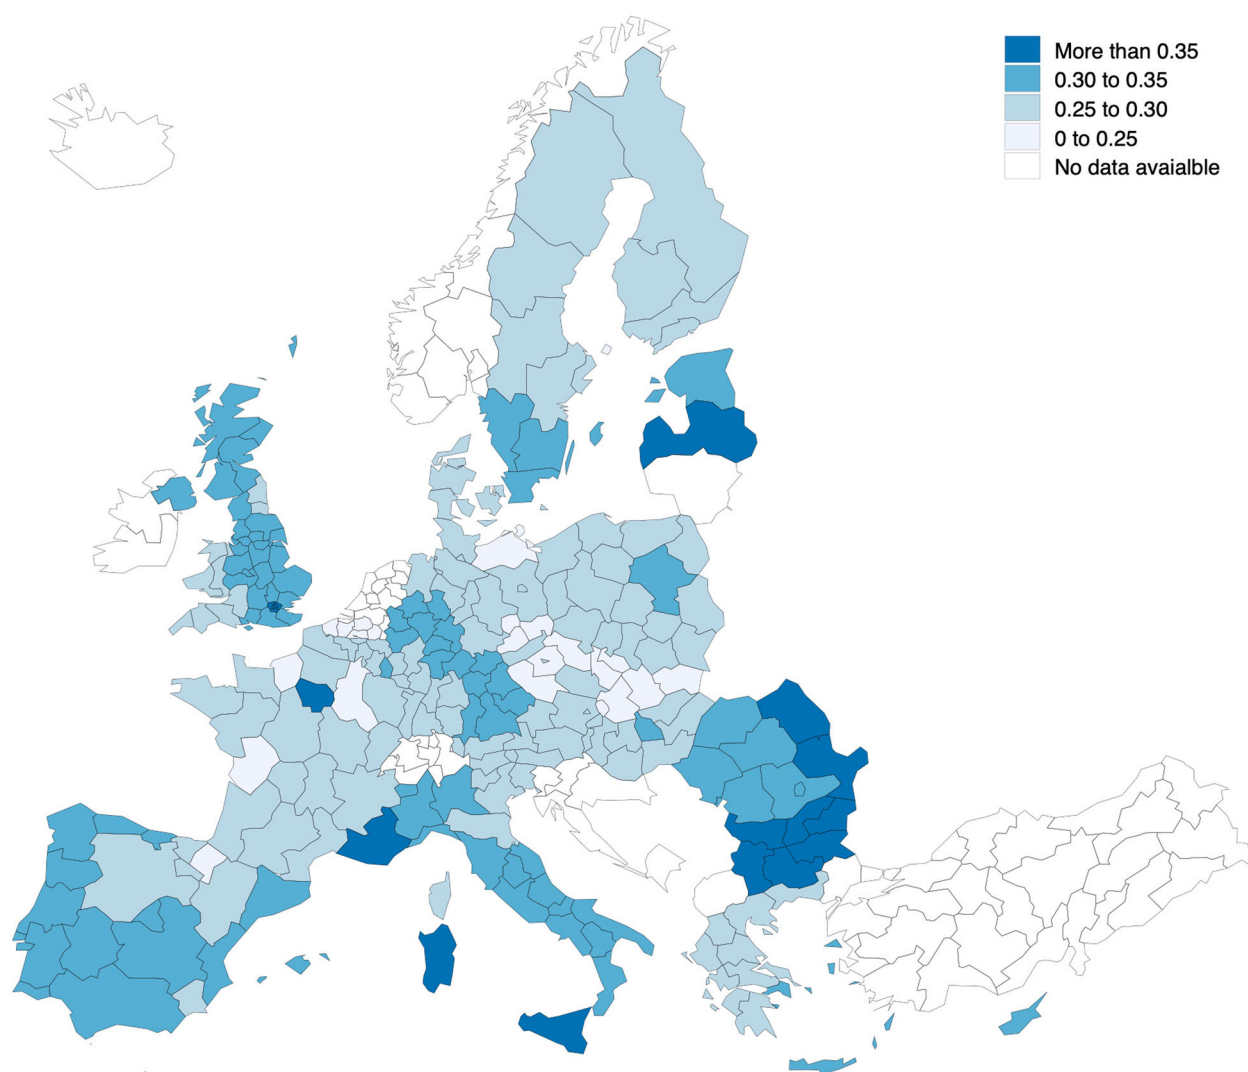

Figure 7. Gini disposable income by region.
Source: Authors' own elaboration.

pandemic than studies conducted at country level have portrayed (e.g., Wildman, 2021).

The results also lead us to reject Hypothesis 2. Excess mortality across regions of Europe during the first 18 months of COVID-19 are far more related to issues of accessibility, pollution, the overall wealth of the region and the education of the population and, in the later waves of the pandemic, the preparedness of the health system than to poverty and inequality.

Another aspect to be considered is the importance of the timing of factors behind the variation of incidence. Our analysis reveals that variations in the incidence of each four waves of the pandemic are related to different factors. The first wave of the pandemic, January–June 2020, caught Europe unaware and unprepared. During this period excess mortality was fundamentally concentrated in more accessible entry points by road and in places with a lower overall government efficiency. It also affected richer European regions to a far greater extent than poorer ones. However, because of this element of surprise, the preparedness of the health system did not represent an

asset. Places with more hospital beds suffered more. In the successive two waves many of the factors potentially driving the incidence of the pandemic changed. Road accessibility remained a key driver of contagion and air pollution began to play a far more prominent role (Conticini et al., 2020). After the first wave, which, in certain ways, was more 'democratic' in its incidence, the pandemic has feasted more on poorer, rather than on richer regions, as well as on those with weaker and less prepared health systems. Population density, a factor that was considered in the early stages of the pandemic as essential for explaining variations in its incidence (Mogi & Spijker, 2022), may have played a very small role (if at all) for the diffusion of the pandemic across regions of Europe.

As the spread of COVID-19 followed geographical patterns, we also test for the presence of possible spatial correlation among our inequality variables, to be sure that the level of inequalities in a region does not influence the excess mortality rates of the neighbouring regions. For this reason, we implement several spatial autoregressive models for the five inequalities indicators and the level

of regional wealth proxied by the GDP per capita. The results are reported in Tables A2–A6 in Appendix A in the supplemental data online. Looking at the bottom part of each table, where the coefficients are linked to the contiguity matrix W , we detect in some specifications the presence of spatial correlation, particularly affecting the regional growth variable. We then compute the direct, indirect and total effects to better understand which are the direct (internal) and indirect (external) spatial spillovers emerging among the inequality variables and excess mortality. The results are reported in the bottom part of each table. The coefficients for the direct (internal) effects are greater than those for the external ones, meaning that the spillover effects on the dependent variable are weak, apart some exceptions like the top 20% and 5% of the income distribution (see Tables A4 and A5 online, respectively). Overall, the results point in the direction that inequalities in a region have had a limited effect on the impact of COVID-19 in neighbouring regions.

5. CONCLUSIONS

Poverty and inequality have traditionally been considered drivers of pandemics. They are generally viewed as two factors that facilitate the spread of all types of illnesses. Research on the incidence of the COVID-19 pandemic has, so far, supported this perception (e.g., Blundell et al., 2020; Palomino et al., 2020; Patel et al., 2020; Rose et al., 2020; Tavares & Betti, 2021; Wildman, 2021): poverty and inequality matter for the impact of COVID-19 and they matter as much, if not more, than other factors behind the spread of the disease. Yet, the evidence that poverty and inequality are at the root of the highly uneven geography of COVID-19 in Europe is so far limited. The limited availability of data on interpersonal inequalities, among other factors, has stymied this type of analysis, leading to a situation whereby the supposed influence of poverty and inequality on the spread of the pandemic has been mostly assumed rather than demonstrated.

In this paper we have sought to fill this gap in our knowledge by assessing the extent to which regional excess mortality rates during the first 18 months of the COVID-19 pandemic in Europe are related to regional poverty, material deprivation, wealth and inequality.

The analysis shows that, in contrast with the dominant assumption and with research conducted for the United States (Tan et al., 2020), poverty, material deprivation, wealth and inequality seem to have a limited capacity to explain the uneven European geography of COVID-19. There is no connection whatsoever between differences in inequality and the incidence of the pandemic. Poverty levels and material deprivation are not related to higher excess mortality, while the presence of pockets of wealthy individuals is connected with more, not less, excess mortality. It seems that, at least in the case of Europe, variations in the lethality of the incidence of COVID-19 are much more related to other factors – regional wealth, accessibility, pollution, education, and the readiness of

the health system – than to the presence of poor people or high interpersonal inequality.

These results may be simply due to the fact that the regional scale is not the best to assess how inequality shapes the diffusion of the disease. Inequality may strike harder at the local, often urban, scale rather than at the regional one. Poverty may have a greater influence on COVID-19-related excess mortality within our neighbourhoods or our cities than at the regional level.

But, on the whole, the results provide significant food for thought and a stimulus to further delve into what is clearly a complex link between wealth polarization and inequality and the uneven prevalence of COVID-19. There is a need to know much more about the exact mechanisms through which poverty and inequality may increase or decrease the risk of contagion and, after contagion, why in some places COVID-19 has had a far more devastating effect on human lives than in others. It might be the case that in Europe – in contrast, for example, to North America – the provision of universal (or nearly universal) health systems has meant that the results of contagion amongst Europe's poor have not been as tragic as on the other side of the Atlantic (Oronce et al., 2020). Lack of health insurance and/or the fear of having to pay high health bills may have discouraged those at the bottom of the income scale in the United States from going to hospital until it was too late, or at all. Widespread and free healthcare across most of Europe will have driven poor individuals with initial COVID-19 symptoms more into hospitals than their often uninsured peers in the United States. Lower levels of inequality and spatial segregation than in the United States may have also contributed to moderate the incidence of the pandemic amongst Europe's poor. And, finally, a more developed welfare system may have shielded greater shares of the European population from exposure to the virus, through generous furlough or similar mechanisms. Universal or equivalent healthcare systems and a more widespread welfare state are likely to have functioned as shields to the most pernicious effects of the pandemic. Hence, protecting and expanding these systems – what is normally known as the European social welfare system – has been not only a significant protection against COVID-19 for the most vulnerable in Europe, but also represents a potential safeguard against future pandemics.

Having said that, there is still considerable need to analyse what determines why some places are – and may continue to be – far more vulnerable to COVID-19 or, for that sake, to any other pandemic, than others. Understanding the drivers of the uneven geography of COVID-19 is fundamental to build the foundations to make sure that our societies are far better prepared for future health and natural challenges and that the most vulnerable are not at greater risk of suffering the consequences of future plagues than the rest of society.

ACKNOWLEDGEMENTS

We are grateful to the editors of this special issue on 'Geography of COVID-19, Local Policy Answers and

Future Challenges for Cities and Regions' as well as to Ben Derudder, the journal editor in charge of this submission, for their feedback, suggestions and support throughout the refereeing process. We also acknowledge the comments of three anonymous reviewers. Participants at online and in-person conferences in Dublin, Milan and Padua provided useful comments and advice.

DISCLOSURE STATEMENT

No potential conflict of interest was reported by the authors.

NOTES

1. The share of relative poverty and the other inequality indices are missing for Germany and the Netherlands. Belgium and the UK only have data available at the NUTS-1 level, while for all other countries information is provided at the NUTS-2 level.
2. Unfortunately, this indicator is not available for regions in Belgium, France, Germany, Poland, and the UK.
3. The SILC survey is also the source of the data for the share of people in the top 20% and top 5% of the income distribution. This index is built as the total equivalized disposable income received by the 20% of the regional population with the highest equivalized disposable income (top quintile) to that received by the 20% of the regional population with the lowest equivalized disposable income (lowest quintile). The same logic is used when considering the share of the population in the top 5% of the income distribution (EUROSTAT, 2020).
