Using movers to identify close election effects

ALEX YEANDLE
Department of Government, London School of Economics and Political Science, UK

Abstract. Many theories of political participation imply that close elections increase voter turnout, but empirical support for this is mixed. One challenge is that close elections occur in unrepresentative places, making it difficult to extend counterfactual inferences across the wider electorate. In this note, I study closeness in an alternative way by leveraging those who move home between elections. With a large-scale longitudinal survey in Great Britain, comparing individuals who move between safe and competitive parliamentary constituencies, I provide evidence that closeness increases campaign contact but generally fails to affect turnout. British movers are politically comparable to the wider electorate, so the results can be cautiously generalised. This contributes to substantive literature on voter and party-led theories of participation, while adopting an empirical strategy seldom used in the study of political behaviour.

Keywords: Voter turnout; political participation; campaigns; methodology

Introduction

Political scientists have long argued that close elections increase voter turnout. For voters, competitive elections increase the likelihood of being pivotal, and this outweighs the costs of participation (Downs, 1957; Franklin, 2004; Geys, 2006a; Riker & Ordeshook, 1968). For parties, they incentivise investment into campaigns, informing the electorate about candidates and pressuring them to take part (Cox & Munger, 1989; Matsusaka, 1995). But despite clear expectations, and strong evidence at the aggregate level, scholars of individual-level turnout remain unsure about these effects. While recent meta-analyses show turnout rates to be higher in competitive areas (Cancela & Geys, 2016; Geys, 2006b), this is not reflected in individual-level survey data (Smets & van Ham, 2013) or experimental work (Enos & Fowler, 2014; A. Gerber et al., 2020). Given the enormity of the voter turnout literature, and continued theoretical focus on closeness, this lack of empirical foundation is somewhat surprising.

In this note I consider a methodological explanation for these mixed results. Many aggregate studies draw cross-sectional comparisons between safe and competitive areas, despite significant, and potentially unobservable, differences between them. Others use panel data, and so leverage a particular, unrepresentative sample of districts that vary significantly in closeness over time. I propose an alternative way to identify close election effects: a mover design. Across a series of off-cycle elections in Britain, I use longitudinal survey data to study individuals who move home between votes. I assume that the closeness of one’s new parliamentary constituency is independent to potential outcomes, and provide evidence that this is not predicted by prior political persuasion or demographic characteristics. While political scientists have long considered how moving home might directly shape electoral outcomes (e.g., Bhatti & Hansen, 2012; Denver & Halfacree, 1992; Hall & Yoder, 2022; Kim, 2023), it is rarely used as an indirect identification strategy in this manner.
Using data from the British Election Study (BES) internet panel (Fieldhouse et al., 2021), I estimate a series of individual-level fixed effect specifications. I class constituencies as ‘safe’ or ‘competitive’ based on multiple percentage thresholds of victory margin, and present results for moving to each. The control group comparison is an individual who moves, but to a similarly competitive constituency. This holds constant the direct effects of moving – social, financial, logistical – which might shape political participation in other ways. This approach avoids erroneous comparisons between different electoral jurisdictions, while continuing to leverage consistently competitive areas, which are excluded in a panel design.

The results suggest that closeness has significant effects on campaign contact, but does not seem to drive turnout decisions. This lends some support to ‘supply side’ theories of close election effects, focused on the campaigning decisions made by parties over cost-benefit calculations made by voters. But they also indicate that campaign pressure has limited impact on turnout itself, in keeping with mixed literature on campaign effects (e.g., Foos & de Rooij, 2017; Jacobson, 2015; Kalla & Broockman, 2018; Selb & Munzert, 2018) while diverging slightly from canonical get-out-the-vote experiments (e.g., Enos et al., 2014; Gerber & Green, 2000; Townsley, 2018).

I also consider the external validity of mover sub-populations. In Britain, movers tend to be demographically different in predictable ways, but are politically quite similar to the wider BES panel. While caution is clearly required, there are reasons to think the findings may have some out-of-sample validity.

The note makes three contributions to the literature. Methodologically, I apply a new technique to old questions of political behaviour. While mover designs are common across the social sciences (e.g., Bjerke & Mellander, 2017; Breetzke & Polaschek, 2018; Hull, 2018; Wheeler, 2012), they remain rare in the study of electoral politics, and so this note takes a step forward. Theoretically, I provide nuanced examination of why existing findings on turnout are mixed, speaking to debates on drawing precise implications from empirical models (see Lundberg et al., 2021). And substantively, I add to work on both voter and party-led theories of political participation (Franklin, 2004), while deepening our understanding of how local context drives political change (Nathan & Sands, 2023).

**Research design**

**Limitations of existing approaches**

How can we learn about the effects of closeness on political behaviour? Existing studies tend to use cross-sectional comparisons *between* places, or over-time comparisons *within* them. Both approaches suffer from different types of selection bias, with implications for the theoretical lessons we can draw.

First, making simple cross-sectional comparisons between safe and competitive areas risks neglecting other factors that might drive turnout or campaign contact. Competitive districts often differ to safe ones in many ways (Gallego et al., 2016), which might co-determine closeness *and* variation in other forms of electoral and campaign behaviour. Without making strong assumptions, we cannot interpret safe districts as a counterfactual version of their competitive counterparts. In section 2.1 of the Supporting Information I make this point empirically, highlighting how different types of voters live in competitive and non-competitive constituencies in Great Britain.

An alternative approach is to use panel data. This involves comparing the same electoral districts (or people living in them) to themselves across multiple elections, where closeness varies...
over time. This adjusts for any time-invariant features of places or people living there that might confound political behaviour.

But leveraging cross-temporal variation introduces a new, subtle, inference problem. Over-time comparisons only work in districts that vary in closeness between elections. But most districts do not vary that much, as I describe in more detail in the section on measuring competitiveness. More importantly, districts that do vary tend to be quite different to the country at large, in ways that fluctuate over time in accordance with changing national election dynamics. I show this in section 2.2 of the Supporting Information.

Using movers

To resolve this pair of problems I use a mover design, focusing on those who move between constituencies over time. Rather than erroneously compare constituencies directly, or focus on the unrepresentative set that change markedly between elections, I study the individuals who happen to arrive in a competitive area with those who happen to not.

The design assumes that the assignment of ‘treatment’ – the closeness of movers’ new constituencies – is independent to future political and campaign behaviour. Plainly put, people do not strategically move based on closeness, and those with greater propensity to start turning out, or be contacted by campaigns, are no more likely to arrive in competitive constituencies.

Theoretically, this seems defensible. While some work in Britain shows migration into left or right-leaning areas is partly driven by self-selection (Gallego et al., 2016), local competitiveness is less visible and less associated with demographic characteristics or partisanship of new movers. In the most recent general election, the 10 most competitive constituencies were evenly split between Labour (4), Conservative (4), Lib Dem and SNP (1 each). And at the individual-level, in the section on measuring competitiveness, I provide suggestive evidence that the prior demographic and political characteristics of movers do not predict the closeness of where they end up.

Case, data and measurement

To explore how closeness shapes voting behaviour, I study a series of general elections in Britain taking place in 2015, 2017 and 2019. British elections use a single-member district plurality electoral system, and a long literature has evidenced the significant time and effort devoted to local campaigning (Johnston et al., 2012; Middleton, 2019). Party strategists, candidates and voters are often encouraged to think locally as well as nationally (Fisher et al., 2016). Unlike countries with more proportional systems, Britain is thus an ideal case to test arguments about the effects of local competition.

Data

I use data from the British Election Study Internet Panel (BESIP) (Fieldhouse et al., 2021), a large-scale longitudinal survey of the British public. Based on respondents’ constituency, I merge this with official election results from the House of Commons Library. Across the elections under study, constituency boundaries remain unchanged.

The BESIP has two advantages over most surveys. The first is its longitudinal structure, surveying the same respondents multiple times. The second is sample size. Each wave interviews...
around 30,000 people, significantly more than most GB-wide public opinion polls. Importantly, this means that there is sufficient statistical power to detect effects, even after subsetting on those who move home.

I use two distinct samples for the analysis. The 2017 sample uses data from waves 6 and 13, fielded just after the 2015 and 2017 general elections respectively. The 2019 sample uses waves 13 and 19, taken just after the 2017 and 2019 votes. Section 1 of the Supporting Information describes the BESIP, and measures used, in further detail.

**Measuring movers**

I define movers as respondents whose constituency changes between survey waves. This does not directly capture whether a respondent changes house, as a respondent might move within the same local area, but rather whether they arrive in a new parliamentary jurisdiction.9

Table 1 demonstrates the size of each group in the elections under study. While only a small proportion of respondents move between the 2015/2017 and 2017/2019 elections, the number that do so is high. More than 1,000 individuals change constituency between each survey wave, all of whom are observed twice – before and after they move – in the two-period panels. This leaves more than 2000 movers in the panel datasets used for the analysis, a larger sample size than many nationally representative surveys and public opinion polls conducted in Britain.

**Measuring competitiveness**

Measuring competitiveness is conceptually challenging. While many studies simply take the constituency-level margin of victory as a proxy, this is unsatisfying as the importance of victory margin is nonlinear; if the margin fell from 15 to 5 per cent, for example, we might expect voters to notice and parties to change strategies. If the margin fell from 60 to 50 per cent, the seat remains ‘safe’ and so turnout is less likely to change in response.

Figure 1 shows general trends in constituency competition across the British elections under study. Panel (a) shows that there is significant variation in margin of victory, but that this doesn’t tend to shift too much between elections. The average constituency had a victory margin of around 23 per cent across this period. Panel (b) reaffirms this point, plotting the change in margin of victory in 2017 (vs 2015) and 2019 (vs 2017). In most constituencies, absolute victory margin changes by less than 10%.

I classify seats as ‘safe’ or ‘competitive’ by whether their victory margin falls above or below given cut-offs. This type of approach is common in British politics, with constituencies won by less than 5 or 10 per cent often described as “swing seats” and a mark of being competitive (McInnes, 2020).
Figure 1. Trends in constituency competitiveness. Panel (a) plots the margin of victory in each constituency for the 2015–2019 general elections. The red line marks the average, which stayed constant at around 23 per cent. Panel (b) plots the change in absolute victory margin for constituencies, compared to the previous election. The distributions are very similar in 2017 and 2019, with the median rising from 7 to 9 per cent across this period. [Colour figure can be viewed at wileyonlinelibrary.com]

Figure 2. Distribution of constituencies with victory margins that a) are beneath each cut-off, b) fall below each cut-off and so become competitive, and c) rise above each cut-off and so become safe. [Colour figure can be viewed at wileyonlinelibrary.com]

Using a discrete approach sidesteps non-linearity concerns in the importance of victory margin. The biggest drawback is that results risk being sensitive to one particular cut-off over another. I present results for all cut-offs between 1 and 20 per cent, to evaluate if results are comparable across this range.

Figure 2 visualises the number of constituencies falling below each margin cut-off, alongside the number that newly enter and leave, at 5 per cent intervals, across each election. As the cut-off...
rises so too does the number of seats (panel a), increasing the pool of constituencies from which a mover design can draw variation. By contrast, there are fewer constituencies that newly become, or cease to be, competitive between elections (panels b–c). This smaller, less representative group are those from which a conventional panel design would draw identifying variation.

Measuring political behaviour

I analyse two facets of individual-level behaviour: voter turnout and exposure to campaign contact. I measure turnout with retrospective participation questions, which are put to respondents in the survey wave immediately following an election to minimise false recall (Dassonneville & Hooghe, 2017). All questions include text saying that many people were unable to vote, to reduce social desirability bias (see Krumpal, 2013).

Talking to people about the General Election on ____, we have found that a lot of people didn’t manage to vote. How about you? Did you manage to vote in the General Election?

Nonetheless, self-reported turnout in the panel remains high. In the immediate post-election waves between 2015–2019, 93, 91.9 and 91 per cent of respondents report having voted. By contrast, the true turnout rate in each election (excluding Northern Ireland) was 66.4, 68.9 and 67.5 per cent, respectively. Unlike the full British Election Study, the internet panel does not provide validated turnout data, so it is not possible to measure false reporting nor adjust for it in the analysis.

Overreporting of turnout is common to national election studies (Jackman & Spahn, 2019), and might place ‘ceiling effects’ on the analysis that make it harder to detect changes. I discuss this possibility in more detail later, particularly given the general null findings in turnout specifications.

In other ways, though, it need not pose a direct threat to causal inference. Overreporting is likely due to continued social desirability, and the fact that BESIP panellists might be more politically engaged than the wider population. Among movers, neither are likely related to the competitiveness of one’s new constituency. And second, any underlying personality traits that drive false reporting are reasonably addressed by using individual fixed effects.

Measuring campaign contact is more straightforward, with a binary question that asks if any of the main political parties contacted respondents. This general measure encapsulates various ways parties communicate with voters, like door-knocking, leafleting, or online advertising. I explore more specific outcomes in section 5.1 of the Supporting Information, alongside the empirical results presented in the main text.

Across the three post-election waves there is more variation in responses, with between 47.7 and 59.8 per cent reporting contact. These results vary for each specific mode of contact, as outlined in the Supporting Information.

Have any of the political parties contacted you during the past four weeks? (Waves 6 & 13)
Have any of the political parties contacted you during the recent General Election campaign? (Wave 19)
Empirical strategy

Estimation

I estimate close election effects across a series of individual-level, two-way fixed effects specifications. For individuals $i$ in constituency $c$ and election year $t$, I regress individual-level turnout or campaign contact $y_{ict}$ on constituency type $\theta_{ict}$, accounting for individual and election-year fixed effects $\gamma_i$ and $\alpha_t$ respectively. Standard errors are clustered at the individual-level throughout.

I use distinct two-period panels for the analysis, studying 2015–17 and 2017–19 movers separately. This makes estimation comparable to a canonical $2 \times 2$ difference-in-differences design, sidestepping recent econometric concerns about the validity of two-way fixed effects (Callaway & Sant’Anna, 2021).

$\theta_{ict}$ is a three-level factor, with the baseline that a mover’s constituency type does not change. This allows us to disentangle effects among movers who relocate from safe to close seats, and from close to safe seats, maintaining a common counterfactual that absorbs any direct effects of moving.

These specifications estimate an average treatment effect on the treated (ATT) in which the treated group is those who move to a different type of constituency. In what follows I refer to this as the “mover ATT”.

$$y_{ict} = \beta_1 \theta_{ict} + \gamma_i + \alpha_t + \epsilon_{ict}$$

Identification

For $\beta_1$ to yield causal interpretation, we must assume that the competitiveness of movers’ destination constituency is independent to potential outcomes (participation or campaign exposure). To test this, I model the type of constituency to which respondents will move as a function of their demographic and political characteristics. I do this for all cut-offs between 1 and 20 per cent, and plot the resulting 20 p-values for each variable in each election in Figure 3 (full results section 3.1 of the Supporting Information). As evidenced by the lack of red and blue dots, which indicate p values below 5 and 10 per cent, respectively, no characteristics consistently breach conventional levels of statistical significance. While independence cannot be empirically proven, these results provide strong suggestive support.

Results

Main effects

The results of the main specifications are presented below. Since the dependent variable is a binary indicator of turnout or campaign contact, the coefficients can be interpreted probabilistically; each mover ATT represents the change in probability that a respondent reports having voted, or being contacted, in the first general election after they move to a given type of constituency. Results are presented across a series of cut-offs for what counts as a competitive seat, ranging from a victory margin of 1 through to 20 per cent.

Minimal effects on turnout. To begin, Figure 4 presents mixed effects on individual-level voter turnout. Looking first at the 2017 election (upper panels), against expectations both sets of models yield negative coefficients. While this makes sense for those moving to safe seats, it is puzzling for those moving to more competitive parts of the country, for whom effects are if anything more robust. Nonetheless, many of the estimates fail to reach conventional levels of statistical significance, and vary substantively across cut-offs.

In 2019 (lower panels) the evidence is similarly mixed. While moving to a safe seat reduces turnout at some of the highest percentage cut-offs, effects elsewhere are inconsistent and usually fail to reach statistical significance, so do not yield firm substantive conclusions.

Overall, these results do not provide strong indication that moving to a safe or competitive constituency affects voter turnout. Part of this lack of effect may stem from over-reporting, or above-average true political participation among panellists, placing a ceiling on the findings. It
Constituency type has mixed effects on turnout among movers

Figure 4. Mover ATT estimates for self-reported turnout. Full results in section 4.1 of the Supporting Information. [Colour figure can be viewed at wileyonlinelibrary.com]

might also highlight selection effects in existing cross-sectional and panel research designs, which sometimes report significant results.

**Stronger effects on campaign contact.** There is stronger evidence that moving to a new type of constituency impacts the likelihood of being contacted by political parties. Figure 5 presents effects on general self-reported contact in the election campaign. Particularly in 2017 (upper left), moving to a safe seat has more consistent negative effects on contact, which are statistically significant at a wide range of cut-offs. Positive effects from competitive constituencies are routinely positive and significant in 2019 (lower right), and point in a similar direction two years before.

One problem with these results, though, is that they rely on a general outcome measure which collates many different types of campaign contact. If competition is driving exposure to campaigns among movers, we might expect these effects to be driven by more costly modes of campaigning, which parties must strategically allocate across seats. One such form of campaign contact is whether or not respondents are ‘visited’ by party activists. Visits, sometimes referred to as ‘canvassing’, are a core part of parties’ mobilisation efforts in British elections (see: Johnston et al., 2012).

Figure 6 presents results using this outcome, and the effects become more marked. Moving to a safe seat sees reported canvassing decline in both elections, while moving to a competitive seat sees it increase in 2019. These effects are particularly robust for safe-seat movers in 2017 (upper
Constituency type shapes the campaign contact experienced by movers

![Graph showing the campaign contact experienced by movers in 2017 and 2019 elections.](Image)

left), where 85 per cent of coefficients are significant at the 10 per cent level, and competitive-seat movers in 2019 (bottom right), where 95 per cent are as such. In section 5.1 of the Supporting Information I examine effects for other modes of campaign contact.

Taken together, these findings suggest that exposure to campaign contact is likely shaped, at least in part, by the type of constituency to which one moves. These effects appear driven by in-person forms of campaigning, to which parties strategically allocate resources based on perceptions of how likely they are to win the vote.

**Robustness.** In section 5 of the Supporting Information I perform a series of additional checks to validate these findings. These are based on different measures of movers, and alternative outcomes.

First, I run a series of specifications that account for how long an individual mover has been living in their new constituency. This includes using additional waves of the BES internet panel that fall between elections, and observing how 2015–2017 movers behave in the 2019 election. With the caveat that these approaches significantly reduce sample size, there are similar effects on contact and some evidence that turnout becomes more sensitive. In particular, those who move to a safe seat and live there for longer periods of time appear to become less likely to vote in the former set of specifications.

Second, I use a wider range of outcome measures in the contact specifications. I show that less targeted campaign strategies, like being approached in the street or by email/social media, are less
Contact effects are driven by targeted, physical modes of campaigning

Figure 6. Mover ATT estimates for party canvassing. Results for other modes of contact in section 5.1 of the Supporting Information. [Colour figure can be viewed at wileyonlinelibrary.com]

consistently impacted by constituency competition. Instead, effects are strongest for canvassing and receiving leaflets.

External validity

The results throughout this research note present effects among movers. But how might these generalise to the wider population, and be of wider theoretical consequence?

One way to gauge the external validity of the estimates is to see how representative movers are of the wider BES sample. I compare the political and demographic characteristics of future movers and non-movers, to understand how movers might differ.

Figure 7 presents the results, from which two key trends emerge. First, movers are not a demographic mirror of the full sample: they tend to be younger, less working class, less likely to own a home, less likely to have children, and more likely to be university educated.

Many of these findings are intuitive, given the logistics of moving. For instance, moving is more difficult for those who own a home or have children, while younger, university educated, middle class people tend to be more geographically mobile in the labour market.

How these differences relate to voter turnout, though, is less clear. On the one hand, existing work suggests that better educated, more middle class voters are more likely to participate in elections (Evans & Tilley, 2017; Smets & van Ham, 2013). So too are voters without children...
Comparing movers to non-movers

Figure 7. Cross-sectional differences in the probability of moving house between elections. Coefficients represent the change in probability of moving, compared to not moving. Remain vote variable not included for the 2015 sample, as the vote did not take place until 2016. Full results in section 3.2 of the Supporting Information. [Colour figure can be viewed at wileyonlinelibrary.com]

(Bellettini et al., 2023; Bhatti et al., 2019), so, a priori, movers should have more proclivity to participate. On the other hand, the fact that movers are younger and less likely to own property might have effects in the opposite direction. There is significant evidence that young people are less likely to vote in elections (Smetts & van Ham, 2013), particularly in Britain (Prosser et al., 2020), while property ownership, as a means to holding a permanent stake in local politics, has long been viewed as a determinant of participation (Brady et al., 1995). Taking all these factors together, it is not clear whether movers are the types of people we should necessarily expect to vote more, or less, than the wider public.

Despite demographic differences, however, movers are generally more politically comparable with the broader sample. They are no more or less likely to have voted in the last election before moving, have similar levels of self-reported political attention, and chose similarly in the EU referendum. The only difference is that 2017 movers are slightly more likely to identify as government supporters (in 2015), but this effect is substantively small (around 1.5 per cent), and significantly smaller than the comparable effects of age and home ownership.

A reasonable conclusion to draw, then, is that while movers are not a perfect snapshot of the general public, they provide a consistent and reasonably politically representative sample. This gives scope for cautious generalisation, potentially more so than in some existing cross-sectional and panel designs.

Discussion

Scholars have long asked how closeness shapes campaign exposure and participation, but have been unable to reach empirically satisfying conclusions. This note takes a step forward, identifying
turnout and campaign contact effects among those who move between British parliamentary constituencies.

I present evidence that moving to a competitive constituency increases exposure to campaigns, particularly for costly, targeted strategies like door knocking. There are mixed effects on turnout; moving to a competitive area does not appear to increase self-reported participation, though there is some evidence, among longer-term movers, that moving to a safe seat sees turnout decline.

These results raise a series of questions going forward. First, they do not sit neatly in voter or party-led theories of political participation. If closeness matters because individual voters feel more or less pivotal, we should expect to see effects in both safe and competitive seats. We do not. Similarly, if closeness matters because it spurs greater mobilisation by parties, turnout should rise in addition to campaign contact. It does not.

There are a few potential explanations for the results, which warrant further investigation. One is that campaigns may respond to closeness (Middleton, 2019) but voters do not respond to campaigns. Another is that campaigns shape the behaviour of few voters (e.g., Foos & de Rooij, 2017; Kalla & Broockman, 2018) and so avoid detection in this study. Campaign effects could in fact shape vote choice rather than turnout (Núñez, 2021; Snow, 2022), an outcome I do not empirically evaluate. And finally, null findings could be accentuated by the overreporting of self-reported turnout in the BES internet panel, and associated ‘ceiling effects’. This would help explain why turnout declines in safe seats under some specifications, but never appears to rise in their competitive counterparts.

As with any mover study, questions remain about generalisability. British movers are demographically distinct to the rest of the BES panel, but do appear to be politically similar across a range of measures. While caution is required, there is clearly some scope for generalisation. Using a mover design also allows us to leverage variation from a wider pool of constituencies, another dimension on which the findings may be more representative than under existing research designs.

While Britain is an apt case in which to study close election effects, any single-country study naturally raises concerns about how findings travel geographically. British elections are characterised by small, single member district plurality constituencies under uniform, national, electoral laws. In settings where voter registration processes vary significantly across jurisdictions (Kim, 2023), or where the overall electoral system is more proportional and closeness harder to define (Cox et al., 2020), it is less clear whether a mover design would be equally beneficial for these questions. Moreover, the composition of mover subgroups will itself vary markedly across countries. Many lower-income democracies, for instance, have high levels of rural-to-urban domestic migration, with this movement capturing far more contextual variation than electoral closeness alone (Kramon et al., 2022; Lee et al., 2021).

Beyond voter turnout and campaign contact, however, using mover designs to study electoral behaviour is itself a methodological contribution. While these designs are not new, their value to political science remains under-appreciated, especially as more longitudinal and georeferenced data become available to researchers. This research note seeks to encourage scholars to leverage movers more often, to study political phenomena around the world, participation and beyond.

Notes

1. For evidence of a positive effect, see Denver and Hands (1974, 1985); Diwakar (2008); Franklin (2004); Heath (2007); Vowles, Katz, and Stevens (2017). For evidence of mixed or null effects, see Rallings and Thrasher (1990); Denver, Hands, and MacAllister (2003); Blais and Rubenson (2013).
2. Examples of work includes Denver and Hands (1974, 1985); Rallings and Thrasher (1990); Pattie and Johnston (1998); Matsusaka (1993); Endersby, Galatas, and Rackaway (2002); Diwakar (2008); Taşkin (2015).
3. While not always concentrating on district marginality, examples of work includes Tenn (2017); Dennison (2017); Vowles, Katz, and Stevens (2017); Moskowitz and Schneer (2019).
4. I study general elections that were UK-wide, but focus only on constituencies in Great Britain (England, Wales and Scotland) as these are the areas sampled by the survey.
5. Gallego et al. (2016) and Cantoni and Pons (2022) are two exceptions, though address different research questions.
6. This is also true when looking at within-individual effects, at least in Britain, as most (>90%) do not move constituency between elections in the 2015-2019 period.
7. Excluding Northern Ireland, which is not included in the BES internet panel and so falls outside the analyses in the paper.
8. See: https://commonslibrary.parliament.uk/tag/elections-data/
9. This therefore slightly underestimates the true number of movers, but such respondents are dropped from the analysis and are likely small in number, so should not directly shape the results.
10. This is akin to a ‘balance check’ specification in a conventional experiment.
