Abstract

**Objective:** There is a growing literature on the relationship between teamwork and patient outcomes in intensive care, providing new insights into the skills required for effective team performance. The purpose of this review is to consolidate the most robust findings from this research into an ICU team performance framework.

**Data Sources:** Studies investigating teamwork within the intensive care unit within Pubmed, Science Direct and Web of Knowledge databases.

**Study Selection:** Studies investigating the relationship between aspects of teamwork and ICU outcomes, or studies testing factors found to influence team working in the ICU.

**Data Extraction:** Teamwork behaviours associated with patient or staff-related outcomes in the ICU were identified.

**Data Synthesis:** Teamwork behaviours were grouped according to the team process categories of ‘team communication’, ‘team leadership’, ‘team coordination’, and ‘team decision making’. A prototype framework explaining team performance in the ICU was developed using these categories. The purpose of the framework is to consolidate the existing ICU teamwork literature, and to guide the development and testing of interventions for improving teamwork.

**Conclusions:** Effective teamwork is shown as crucial for providing optimal patient care in the ICU. In particular, team leadership appears vital for guiding the way in which ICU team members interact and coordinate with others.

**Key words:** ICU; Teamwork; Team performance framework; Training interventions; Patient safety; Leadership
Teamwork refers to the way in which team members function and coordinate to produce ‘synchronised’ output (1). Patient safety research has demonstrated that poor teamwork is a causal factor underlying critical incidents in the intensive care unit (ICU) (2). Due to this, a growing amount of research has been conducted within the ICU in order to identify the specific components of teamwork that influence patient outcomes (3,4). The main purpose of this research is to guide the design of training materials and workplace interventions to improve teamwork. However, at present the findings from studies investigating ICU teamwork are disparate and lack synthesis, therefore the extent to which they can influence practice, training and future research is limited. This review takes an industrial psychology perspective to summarise the ICU teamwork literature, and develops a conceptual team performance framework tailored for intensive care medicine.

**Team performance frameworks**

Psychology researchers in high-risk industries (e.g. aviation, military, nuclear power) have found effective teamwork as crucial for maintaining safety within these domains (5,6). In order to better understand the relationship between teamwork and performance in these settings, team performance frameworks (or models) have been developed. These show team outputs (e.g. team effectiveness, performance, errors) to be influenced by group ‘processes’ related to team communication, leadership, coordination and decision-making (7-11). Furthermore, group processes are influenced by a range of ‘inputs’ (e.g. group structures, member characteristics, work tasks) (12-14). The purposes of team performance frameworks are three-fold. Firstly, they systematise the mechanisms that predict team performance, thus facilitating the
design and structure of evidence-based team training materials and interventions for improving teamwork. Secondly, they detail the conditions, structures and procedures known to be indicative of effective teamwork, therefore providing valuable information for the training and assessment of teamwork skills. Lastly, team frameworks guide the evaluation of teamwork interventions through developing a structure against which to test expected change (e.g. attitudes, behaviours, performance).

In aviation, team performance frameworks have been used to develop sets of team competencies for flight crews (15). With respect to healthcare, it is necessary to develop tailored team performance frameworks that reflect the demands of specialities such as intensive care medicine (16). This paper reviews the ICU teamwork literature in order to consolidate knowledge on the relationship between teamwork structures, behaviours and performance in the ICU, and to begin the development of a team performance framework. It uses a standard group process model from psychology to consider studies that have collected data on the relationship between teamwork behaviours and ICU outcomes.

**Method**

The identification of ICU teamwork related studies involved a search of the Pubmed, Science Direct and Web of Knowledge Psychology databases for papers on teamwork in the ICU published since 1990. The search terms, method and inclusion criteria are shown in figure 1. Articles captured by the search strategy (initially 984 articles) were selected (by TR) on the relevance of their titles and abstracts with respect to whether
the article considered the topic of teamwork and performance in the ICU. The remaining articles (n=59) were then filtered in order to ascertain whether they actually provided empirical information on the relationship between ICU teamwork and outcomes (whether quantitative or qualitative). An examination of reference lists from the filtered articles (n=31) uncovered a further 4 items.

**Results**

In total 35 studies were identified as having investigated teamwork in the ICU. This set incorporates 31 peer-reviewed articles (of which 29 were published in medical journals), two book chapters and two peer-reviewed conference papers. Among the articles was a human factors error analysis of critical incident data that reported on 10 studies of error in the ICU (17). This paper was included rather than the individual critical incident studies discussed in it. The data collection methods used for the 35 studies included in the review varied considerably, and are listed in table 1.

**Insert Table 1 Here**

Of the papers not included in the final selection, many did not empirically investigate teamwork, and focused on topics such as education, promoting multidisciplinary teamwork, decision-support mechanisms and communicating with patients. The sections below discuss the key findings from the 35 studies that were identified by the search strategy. The findings are considered in terms of four teamwork processes.
(team communication, team leadership, team coordination and team decision-making) identified as crucial for predicting team performance within the psychology teamwork literature (7-14).

**Team Communication**

*Team communication* relates to the transfer of information, ideas and opinions between the members of a team (18). Observations of ICU teams (19) have shown errors in the ICU to be concentrated after communication events (e.g. shift changes and handoffs) and 37% of errors to be associated with communication between nurses and physicians. Pronovost’s group at John Hopkins University have analysed ICU adverse event/critical incident data from incident reporting systems (20-22). Their analysis has identified recurring team communication failures that lead to patient harm, with written and verbal communications during routine care, hand-offs, and crises being found most susceptible to error. More specifically, they found critical incidents to occur due to a reluctance of nursing staff to report observed errors or patient care issues, a lack of communication between clinicians and nursing staff on treatment changes, inaccurate information transfer between different ICU care teams and poor information dissemination on newly admitted patients. Survey and interview research have also examined the relationship between ICU team communications and patient outcomes (23), with timely, accurate and open communication between nurses and physicians being shown as predictive of patient length of stay and staff turnover (24).
Observations in high-fidelity simulator studies have studied team communication behaviours. Video analysis of teamwork during simulated patient resuscitations has found the communication skills of ICU residents to be rated most highly if they communicate clearly at all times, encourage team member input, listen to staff feedback, and consistently use directed verbal and non-verbal communications. Conversely, the communication skills of residents are rated most poorly when they fail to acknowledge staff communications and do not use directed verbal and non-verbal communications (25). High-fidelity simulator research has also established a relationship between team communication and technical performance (26), with ICU teams being assessed during the management of septic shock. Teams were rated highly if team members made clear and direct requests, employed closed loop communications, communicated the urgency of patient problems and shared information on the patient care plan. Teams were rated poorly if team members did not request appropriate information, or did not communicate treatment priorities and problems with patients. Teams rather than individuals were assessed and correlations were found between ratings on technical performance (e.g. making diagnoses) and scores on the behavioural aspects of performance (e.g. communication).

Thomas and colleagues (27) have built on measurements for assessing teamwork in commercial aviation in order to develop an observational rating system for assessing teamwork skills during neonatal resuscitation. Their research has investigated the relationship between assessments of teamwork and non-compliance with Neonatal resuscitation standards during 132 videoed neonatal resuscitations (27). The frequency with which NICU teams were observed to demonstrate team behaviours related to communication (e.g. information sharing, asking questions about infant
status or treatment plans), and also management and leadership, were found to be weakly correlated with compliance for Neonatal resuscitation standards. Furthermore, interns who received team training as part of neonatal resuscitation training were shown to display more teamwork related behaviours (e.g. information sharing) than those who did not receive training (28).

Survey research has investigated aspects of team structure, and in particular how status hierarchies influence perceptions of teamwork (29,30). For example, a majority of physicians report highly positive perceptions of communication openness between nurses and physicians, as compared to just over a third of nurses (30). A similar difference was found between senior and junior physicians. Survey research has also shown that ICUs with teams reporting high levels of group development (e.g. whether team members trust one another, discuss goals. and are not in conflict) have lower risk-adjusted mortality rates (31). Observational research during the ICU round has shown team member roles to influence interruptive behaviours, with physicians interrupting other caregivers roughly twice as often as nurses do (32). Ethnographic work in Canada has identified factors that influence whether ICU team members communicate collaboratively (33). These include whether the team has a shared perception of who was in the decision-making role during a specific scenario; whether team members work together to reach an understanding on patient conditions, and whether there are demanding time constraints on the delivery of care.

Team communication research in the ICU has shown communication to be linked to safety and performance, and that team structures and characteristics influence teamwork. Research in military and aviation has found similar trends (34), with team
leadership being identified as particularly important for structuring and regulating team communication processes (35).

**Team Leadership**

Data from ICU critical incident studies have indicated the importance of effective *team leadership* for safety (17,22). Team leadership refers to the guidance of a team (36), and involves defining goals, setting expectations, organizing team resources and coordinating team activities (37). Studies of leadership in industry and acute medicine tend to concentrate on four levels; action leaders (e.g. ad-hoc emergency teams), operational leaders (e.g. unit-level supervisors), tactical leaders (e.g. departmental managers) and strategic leaders (e.g. board level directors) (38-40). Leadership research in the ICU mostly focuses on the ‘action’ level. For example, simulator and real-life observations have shown associations between ratings of performance and leadership behaviours such as encouraging team member input, stating and evaluating plans, asserting opinions when appropriate, listening to staff feedback, delegating tasks effectively, prioritising aspects of care and ensuring team member comfort with allotted duties (25-27).

Simulator research has shown that team performance during cardiovascular resuscitation is optimal when the first arriving team leader (e.g. senior nurse, junior physician) demonstrates more immediate directive leadership behaviours (i.e. coordinating the teams), and when the late arriving senior physician systematically evaluates the situation and guides the team rather than taking charge immediately (41). Stockwell and colleagues (42) have investigated the impact of physician
management skills on the care provided to paediatric ICU patients. Using the Physician Management Index (PMI), 827 residents and fellows rated daily the ability of 8 attending physicians on 20 dimensions, including their ability to effectively lead and communicate with the ICU team, to manage resources, to set high standards, and to provide support on issues of performance and team development. The study found higher overall daily ratings by staff for attending physicians on the PMI were associated with higher numbers of patient goals being completed during NICU shifts. However, due to the small sample of physicians being assessed, it is not clear which specific attitudes/behaviours lead to this association.

Although effective team leadership appears important for the ICU, there are still relatively few in-depth investigations of senior physician leadership skills (43). Data from trauma centres, which face many similar challenges to the ICU, provide interesting insights into the nature of team leadership in acute healthcare teams. Observational and interview research with trauma centre teams has shown that team leaders demonstrate ‘dynamic delegation’ behaviours, whereby the senior physician delegates and withdraws the leadership role to junior physicians in order to spread the intense workload and to build junior physician confidence (44). Furthermore, scenario-based research investigating leadership during trauma resuscitation has indicated that leadership behaviours vary according to the situation. Team leaders show more directive leadership behaviours when the severity of trauma is high, or when a team is inexperienced (45). However, when trauma severity is low, or teams are highly experienced, team leaders delegate more responsibility to junior team members. This indicates the ‘contingent’ nature of team leadership within the ICU, whereby leadership behaviours are adapted according to the situation (46).
Research in neonatal ICUs has also indicated that the leadership style of the team leader influences teamwork. Specifically, leader inclusiveness (e.g. listening and encouraging junior team member ideas) has been shown to result in team members becoming more involved in ICU quality improvement programmes (47). Such research resonates with a long tradition of psychology research investigating leadership style (48,49). Additionally, leadership oriented interventions that focus on training teamwork skills (e.g. conflict management) to senior nurses and physicians are shown to result in staff having positive perceptions of unit leadership (50). However very little research has been published on how ICU senior physicians lead medical teams whilst managing ICUs on a day-to-day basis, and a better understanding is required of how team leadership behaviours influence the communication and coordination behaviours of ICU team members.

**Team coordination**

*Team coordination* refers to the concerted and synchronous performance of work activities by team members, with each team member maintaining an awareness of one another’s work (51). Researching team coordination can be challenging, as it is difficult to distinguish between these behaviours, and team communication and leadership behaviours. Both of these are precursors (e.g. distributing workloads) and integral (e.g. information transfer) for effective team coordination, yet do not fully account for how team members adapt their activities to dovetail with one another.
Analyses of teams managing critical events during crisis management training has indicated errors to result from poor coordination, for example nurses being overloaded with requests, poor task delegation and a lack of prioritisation for care activities (52). Additionally, attitudinal research with ICU staff has found positive perceptions of team coordination (e.g. timely information transfer, awareness of team member activities, team member role clarity) to be associated with lower error rates (53). Survey research has also shown high levels of cooperation between ICU nurses and physicians to reduce reports of staff burnout (54). Observations during the real-life provision of ICU care have been used to study the behaviours ICU team members use to coordinate activities together. These behaviours include nurses cross checking physician-generated patient care plans, physicians and nurses providing ‘heads-up’ alerts to each other about pertinent information outside of the rounds and patient summaries being used to recap the discussion and highlight the core duties of team members (55,56). Lastly, structured observations in the NICU have shown effective workload management (i.e. task distribution and prioritisation) to be associated with independent measures of neonatal resuscitation quality (27).

Although team coordination is determined by factors such as team communication and team leadership, attempts have been made to restructure ICU tasks to improve coordination. For example, an intervention to improve patient transfers between surgery and ICU has adopted coordination principles from *Formula 1* racing pit-stop teams (57). Through segmenting the handover process into different stages (pre-handover, equipment and technology handover, information handover, discussion and planning), using checklists, and assigning ICU and surgical team members clear roles, there were improvements in teamwork (e.g. less omissions of patient information) and
fewer technical errors (e.g. equipment preparation) during intra-team handovers. Interventions have also focused on ICU rounds to make them more concise; to ensure patient care plan information is explicit; to ensure decision-makers are present, and to generate a secure team-based environment (58). This resulted in ICU staff reporting a better understanding of patient care plans alongside higher levels of satisfaction with rounds. Furthermore, adopting daily goal sheets (which structure the round process) has been shown to result in ICU residents and nurses better understanding their patient care duties, and in turn reduced patient lengths of stay (59). This resonates with the psychology ‘shared mental model’ literature, whereby teams communicate and coordinate more effectively when members form a shared mental model for goals, tasks and team member roles and responsibilities (60). These shared mental models facilitate team decision-making, which has also been of interest to ICU researchers.

**Team decision-making**

*Team decision-making* relates to decision-making (either by the leader on behalf of the team or amongst the members of a team) through integrating information and perceptions from the members of a team (61). As with team coordination, team decision-making is influenced by team communication and leadership. In the ICU, collaborative decision-making has been linked to improved patient outcomes. For example, units with higher levels of collaboration between nurses and physicians during patient-transfer decisions have lower rates of risk-adjusted mortalities and higher levels of nurse and resident job satisfaction (62). High levels of collaboration have also been suggested to potentially improve end-of-life care (63). Poor decision-making processes, for example the application of inappropriate plans and the use of
unsuitable techniques, have been shown to contribute to the occurrence of critical incidents (17). Clinician encouragement of team member communication and contributions during the ICU round patient decision-making process is associated with a reduction in adverse event rates (64). Furthermore, nurses and physicians tend to agree that junior team members should be able to question senior physician decision-making and that decision-making should include junior team member input (65).

Observational research in the ICU by Patel and Arocha (66) has shown that levels of collaboration during decision-making processes are influenced by the severity of patient conditions. When patient illnesses are well understood, team communication processes tend to be more ‘democratic’, and decisions are made after contributions from all team members. However, for more complicated patients, senior physicians tend to make key decisions autocratically, and with nurses communicating after performing information-gathering tasks. This reflects findings from trauma centres, which indicate team leaders to adapt their behaviours according to the situation. In particular, during high pressure phases of work, senior physicians adapt their behaviours to effectively lead the team (e.g. through adopting a swift and autocratic decision-making style) (45,67). This is aligned with the literature on decision-making and incident command within the military, emergency services, and aviation industries (68). Perceptions of caregiver involvement during decision-making in the ICU have also been shown to be influenced by team member-role. When asked to report perceptions of involvement in patient decision-making during the ICU round, senior nurses and junior physicians tend to report feeling uninvolved compared to senior physicians (69). This is consistent with survey research showing that nurses report finding it difficult to speak-up during decision-making, with fewer nurses than
physicians feeling that disagreements in the ICU are properly resolved, or that input from nurses about patient care is well received (70). Furthermore, ICU management tend to overestimate the extent to which nurses will have positive attitudes towards teamwork, with variations in attitudes even existing between the ICUs of a single institution (71).

**Discussion**

The findings from the ICU research investigating teamwork are incorporated into a prototype team performance framework for the ICU (Figure 2). In the framework, team processes are sub-divided into the processes of communication, leadership, coordination and decision-making. These processes (and behaviours drawn from the literature that are indicative of effective team processes) are shown as influencing ICU ‘outputs’. Additionally, the inputs of ‘team’, ‘task’, and ‘leader’ are listed. These are factors which have been shown in either the ICU or general psychology literature to influence teamwork processes (7-14). The concepts included in the framework are limited to those that have been directly addressed in the ICU teamwork literature. However, it must be noted that there a number of teamwork concepts within the applied psychology literature that have yet to be investigated within the ICU, yet have been shown as important for safety and performance in other high-risk settings. For example, shared mental models for teamwork and taskwork information (72), team adaptability to changing circumstances (73), and the influence of organisational culture upon teamwork behaviours (74,75) are just some of the additional factors known to influence team performance. Furthermore, the framework does not necessarily illustrate the frequent changes in team composition that occur in ICU, the
influence this can have on performance (73), or the techniques that are used to mitigate the impact of constant changes in team personnel (e.g. having a well-established understanding of team roles (76)). Lastly, it is worth noting that the framework better reflects the leadership structure in ‘closed’ ICU, where unlike in ‘open’ ICUs, leadership and decision-making tends to rest with the intensivist (77).

There are a number of issues for discussion regarding this literature review. Firstly, the article search strategy focused on the relationship between teamwork and performance outcomes. It did not fully consider the consistency or quality of the ICU teamwork measurement tools. For example, data have been published on safety climate surveys containing subscales that focus on attitudes towards teamwork (65,71 78), and several observational measures have been developed to assess teamwork (25- 27). It was beyond the scope of this review to assess or compare measures for their reliability or validity. However, there does exist a need to develop a comprehensive listing and review of the various tools available for measuring teamwork in the ICU.

It is also necessary to consider the types of data (self-report, observational, attitudinal, interviews) that have been collected to understand teamwork in the ICU (table 1). Each have well-documented limitations (79), such as the Hawthorn effect (80) or common method bias (81), and studies vary considerably in design, sampling strategies and statistical analysis. For example, surveys and observations in simulators tend to associate quantitative data measuring teamwork and patient/team outcomes, whereas real-life observations and interviews tend to generalise from the behavioural patterns observed by investigators or practioner reflections on teamwork. This makes
it difficult for this review to compare the weight or significance of individual study findings.

Lastly, it was found that the majority of reviewed studies supported the relationship between teamwork and ICU performance. As with any review of published literature, it is likely to be influenced by a publication bias (82). However, it is noticeable that a number of papers reported non-significant relationships between teamwork and outcome data. For example, although teamwork interventions and perceptions of teamwork are often associated with reduced patient length of stay, they are rarely associated with risk-adjusted mortality (24, 42). Furthermore, when ICUs are compared against one another, units with higher ratings of teamwork do not necessarily perform better on measures of unit performance (23). Lastly, many studies use correlation analyses to test the relationship between measures of teamwork and measures of performance. More complicated predictive analyses are required to fully understand the relationship between teamwork processes and technical or organisational outcomes. This in itself poses numerous difficulties, for example ensuring that study sample sizes are adequate and that teamwork metrics are reliable. Furthermore, there is need to develop longitudinal research designs and to identify a wider range of ICU outcome data that can be used for assessing team performance (16,83).

Conclusions

The prototype team performance framework (figure 2) consolidates the existing knowledge regarding teamwork and outcomes in the ICU, and provides a structure
against which to design and evaluate teamwork interventions. An emerging direction for future research is the relationship between team leadership and team performance. Due to the hierarchical nature of acute medical teams, the behaviours of senior physicians appear to significantly influence the perceptions and behaviours of other team members. In developing interventions and team training programmes, it is therefore critical to fully understand the role of leadership in ICU teams.

Team processes

Team communication
- Information transferred accurately during written/verbal handoff
- Information disseminated on newly admitted patients
- Information distributed on patient treatment plans
- Appropriate information requests during patient emergencies
- Directed verbal and non-verbal communications
- Team members acknowledge communications (closed loop)
- Clear and direct requests made for team member assistance
- Junior team members show speaking-up behaviors

Team leadership
- Appropriate and clear delegation of workload
- Aspects of care are prioritised
- Discussions on patient treatment recapped
- Team member input encouraged, and feedback listened to
- Ensuring team members are comfortable with care plans
- Leadership and responsibility delegated when appropriate
- Directive leadership during crises
- Through situation assessment on late arrival during emergency

Team coordination
- Team members are aware of one another’s activities
- Workload is distributed evenly and according to ability
- Core duties for team members are clearly outlined
- Timely information transfer between team members
- Plans are ‘cross-checked’ to ensure a shared understanding
- Team members provide ‘heads-up’ for critical information

Team decision-making
- Collaboration during decision-making processes when appropriate
- Junior team members able to discuss decisions with team leader
- Input from junior team members well-received
- Junior team members focus on info gathering for complicated patients
- Reduced discussion during emergencies and extreme pressure

Input
- Team
  - Team hierarchies
  - Team member roles
  - Team climate
  - Team communication norms
  - Individual team member knowledge and experience
  - Individual team member attitudes and personalities
  - Team member expectancies of one another
  - Motivation, and ability to cope with stress
  - Teamwork training

Task
- Task structure
  - Protocols for completing task
  - Checklists
  - Requirement for team member collaboration
  - Complexity and importance of task
  - Time pressure
  - Available resources
  - Ergonomic design of work environment

Leader
- Leadership style
  - Technical skills and prior task experience
  - Personality
  - Attitude towards team working
  - Delegate and prioritisation skills
  - Ability to assess abilities of team member
  - Resilience to stress

Output
- Patient outcomes
  - Adverse events and critical incidents
  - Patient mortality
  - Patient length of stay
  - Quality of end of life care
  - Unit efficiency
  - Compliance with protocols
  - Technical performance

- Team outcomes
  - Satisfaction with team working
  - Job satisfaction
  - Staff morale
  - Stress
  - Burnout
  - Staff turnover
