A B S T R A C T
Emerging economies, particularly those dependent on commodity exports, are prone to highly disruptive economic cycles. This paper proposes a small open economy model for a net commodity exporter to quantitatively study the triggers of these cycles. The economy consists of two sectors, one of which produces commodities with prices subject to exogenous international fluctuations. These fluctuations affect both the competitiveness of the economy and its borrowing terms, as higher commodity prices are associated with lower spreads between the country’s borrowing rate and world interest rates. Both effects jointly result in strong positive effects of commodity price increases on GDP, consumption, and investment, and a negative effect on the total trade balance. Furthermore, they generate excess volatility of consumption over output and a large volatility of investment. Besides explicitly incorporating a double role of commodity prices, the model structure nests the various candidate sources of shocks proposed in previous work on emerging economy business cycles. Estimating the model on Argentine data, we find that the contribution of commodity price shocks to fluctuations in post-1950 output growth is in the order of 38%. In addition, commodity prices account for around 42% and 61% of the variation in consumption and investment growth, respectively. We find transitory productivity shocks to be an important driver of output fluctuations, exceeding the contribution of shocks to the trend, which, though smaller, is not negligible.

1. Introduction
Emerging economies, particularly those dependent on commodity exports, have a long history of volatile and disruptive economic cycles. A rich literature in International Macroeconomics has proposed several explanations for these cycles, pointing to different plausible triggers or underlying sources of shocks. The relative importance of the various triggers, however, still divides the literature. Aguiar and Gopinath (2007) argue that the main source of fluctuations is nonstationary total factor productivity (TFP) shocks - the cycle is the trend. García-Cicco et al. (2010) refute the argument, showing that these shocks only explain a negligible fraction of fluctuations. They contend that the main drivers of shocks are stationary TFP shocks as well as exogenous shocks to the country’s interest rate. The latter result relates to work by Guimaraes (2011), Neumeyer and Perri (2005), and Uribe and Yue (2006), who highlight the role of changes in global interest rates as a potential driver of the cycle. The role of commodity prices and, more generally, terms of trade, has been equally divisive. Mendoza (1995) and Kose (2002) argue that fluctuations in the terms of trade explain a large fraction of the output variance. However, empirical work by Schmitt-Grohe and Uribe (2017) has raised questions on the ability of terms of trade to match critical features of business cycles in emerging economies. Interestingly, though, estimates by Fernández et al. (2017) suggest that fluctuations in commodity prices account for a significant

fraction of output fluctuations. For economies with a comparative advantage in the production of commodities, fluctuations in the terms of trade and in real commodity prices tend to display a highly positive correlation, and hence the tension between these two empirical studies’ results invites a fresh take. In turn, these results call for a tighter connection with the aforementioned studies on the relative importance of different productivity and interest rate shocks. This paper seeks to quantitatively assess the drivers of emerging economy business cycles using a unified model that nests the various sources of shocks advanced in the literature. The model builds on the small open economy setting of Aguiar and Gopinath (2007) and García-Cicco et al. (2010) by adding two elements absent from their analysis. First, it allows for a second sector to capture the separate role of commodities in the economy. Specifically, the analysis focuses on the case of a net commodity exporting country facing exogenous international price changes. Second, the model embeds a negative relation between the interest rate premium and commodity prices. The relevance of this channel has recently been highlighted by Fernández et al. (2015) and Shousha (2016), and is consistent with the empirical evidence.

To study the predictions of our model, we resort both to a calibration exercise and to the estimation of the model with Bayesian methods. The quantitative analysis throughout the paper focuses on Argentina, a quintessential example of a commodity exporting emerging economy. Given the lengthy duration of Argentine cycles, we carry the analysis over a long period (1900–2015) in order to capture multiple cycles. To set the stage, we begin by revisiting a number of empirical regularities. In common with other emerging economies, Argentina displays large and persistent cyclical fluctuations, excess volatility of consumption over output, high volatility of investment, and a negative correlation between output growth and the trade balance. In addition, the Argentine data reveal large positive effects of world commodity price shocks on output, consumption, and investment, as well as negative effects on the trade balance. We identify these shocks using a structural vector autoregression (SVAR) model with a standard Cholesky decomposition, relying on the assumption that world commodity prices are not contemporaneously affected by Argentina’s economic activity. Furthermore, the data display a strong negative association between interest rate spreads and real commodity prices. Maintaining the assumption that international commodity prices are exogenous to developments in Argentina’s economy, we estimate this relation with a set of regressions of measures of Argentine real rates (net of world interest rates) on an international commodity price index and various controls. The strongly negative relation is robust across a number of specifications, with different spread measures and different sets of controls, including output growth, the trade balance and the debt-to-GDP ratio. The lower bound of our estimates suggests that a 10% deviation of commodity prices from their long-run mean can move Argentina’s real interest rate spread by almost 2 percentage points. This finding confirms the existing evidence from the literature on interest rate spreads of commodity exporting economies (see in particular Bastourre et al., 2012, Fernández et al., 2015 and Shousha, 2016). It also connects with earlier work by Kaminsky et al. (2005) on the procyclicality of capital flows in developing countries.

In the model calibration exercise we analyze the response of the economy to commodity price shocks of a sensibly calibrated size, which we can directly compare to the impulse response functions obtained from the SVAR. We find that the model impulse response functions line up well with their empirical counterparts. The two effects stemming from commodity prices (that is, the competitiveness effect and the borrowing cost effect) jointly produce impulse response functions to a commodity price shock that match the empirical responses. They generate strongly positive effects on GDP, consumption, and investment, and a negative effect on the total trade balance. They also give rise to a somewhat larger response of consumption over output. We show that the first effect alone (akin to a productivity increase) cannot generate a countercyclical trade balance. Similarly, the second effect alone (which is isomorphic to a simple negative interest rate shock) does not give a contemporaneous response in output, while consumption and investment do increase on impact. The net contribution of the two effects can reproduce the empirical regularities.

The aim of the structural estimation of the model is to gauge the quantitative importance of commodity price shocks, relative to other shocks, in driving the business cycle. We apply Bayesian estimation methods, using data on output, consumption, investment, and the trade balance of Argentina. We estimate the stochastic processes of various exogenous disturbances, as well as the two parameters governing the sensitivity of the interest rate spread to commodity prices and to the debt level. Our results suggest a sizeable contribution of commodity price shocks to Argentine business cycle fluctuations. The posterior forecast error variance decomposition based on data from 1900 to 2015 attributes 22% of the observed variation in output growth to commodity price shocks. Furthermore, 24% of consumption growth and 34% of investment growth can be accounted for by commodity price shocks. Reassuringly, the model-implied process for the commodity price shocks shares important features with empirically observed world commodity prices. Since it mimics the data particularly closely after 1950, we carry out the estimation on the post-1950 subsample and find that the contribution of commodity price shocks to output, consumption, and investment growth rises to around 38%, 42%, and 61%, respectively.

Our assessment of the remaining variation in macroeconomic aggregates sheds additional light on the debate about the candidate drivers of emerging economy business cycles previously proposed in the literature. We find that, in general, stationary technology shocks remain the most important source of fluctuations, explaining around half of the variation in output growth. These stationary shocks to TFP are quantitatively more important than non-stationary TFP shocks. While this echoes the conclusion of García-Cicco et al. (2010), who question the notion that the “cycle is the trend” in emerging economies, the contribution of nonstationary shocks remains non-negligible, as these shocks are able to explain 21% of the variation in output growth in both samples used in the estimation. We also find a significant role for preference shocks and interest rate shocks in...
explaining the variation in consumption, investment, and the trade balance. Taken together, our results suggest that commodity prices should feature prominently in the analysis of business cycles in emerging economies. In terms of quantitative contribution, they are among the three most important shocks driving output growth in Argentina. Importantly, shocks to international commodity prices, in contrast to inherently more opaque concepts such as domestic TFP shocks, are factors that are easier to identify and measure, and potentially act upon, by policy makers.5

The rest of the paper is organized as follows. Section 2 presents a number of empirical regularities characterizing Argentine business cycles. As said, many of these regularities are shared with other emerging commodity exporting countries, though for the sake of accuracy in the mapping from the data to the model, we think it is appropriate to focus on a single country. Section 3 introduces the model. Section 4 performs the calibration exercise and studies the role of commodity price shocks in the model. Section 5 estimates the model and carries out a quantitative analysis of the various sources of shocks; it also discusses practical issues concerning the measurement of real GDP. Section 6 contains concluding remarks.

2. Emerging market cycles: empirical regularities

This section presents the main empirical features that characterize the business cycle of Argentina’s economy from 1900 to 2015.

2.1. Data and sample

Although there are strong commonalities across emerging countries, we think it is important to work with a straight mapping from a single country to the model, rather than using averages across different countries, which might confound effects due to aggregation. The focus on a long time period is both insightful and befitting for a case for analyzing fluctuations jointly over the entire period.6 Third, Argentina’s cyclical properties have shown virtually no changes over this long period. This is apparent in Fig. 1, Panel (a), which plots the logarithm of Argentine real GDP per capita from 1900 to 2015. Argentina’s output volatility in the first half of the 20th century (measured as the standard deviation of real GDP growth rates) is practically the same as the volatility in the post 1950 period, despite the higher levels of development in the latter part of the sample. In the corresponding plot for the United States, shown in Panel (b), marked changes in the volatility of output are visible. This typically leads researchers to separately analyze data before and after the World War II, or before and after the 1980s, which was when the Great Moderation occurred in the United States. Such changes in volatility are not present in Argentina, which supports the case for analyzing fluctuations jointly over the entire period.7 Third, Argentina’s trend growth rate has been remarkably stable since 1900, at 1.2% per year, a constancy that can be fully appreciated by taking a long-term perspective in analyzing its business cycles.7 In addition to output data, we will focus on typical macroeconomic variables of interest in small open economies, by studying the fluctuations of consumption, investment, and the trade balance. The data come from a variety of sources, including most notably Ferreres (2005).8

Furthermore, since our aim is to assess the importance of commodity price fluctuations for Argentina’s economy, we need to select an appropriate commodity price index. Our preferred index is the one constructed by Grilli and Yang (1988), which we update following Paffenizzer et al. (2007). The index is available from 1900 and reflects world commodity prices, which is advantageous because developments in global prices are arguably exogenous to economic conditions in Argentina (see further discussion below). The drawback, of course, is that it may capture price developments of commodities that are unimportant, or even absent, in Argentina’s commodity export composition.9 We therefore cross-check this index with an Argentina-specific commodity price index, which we construct using commodity price data provided by the World Bank, together with trade weights available from the UN Comtrade database. This construction is possible from 1962 onwards. Fig. 2, Panel (a), plots the two indices (in nominal terms) and shows that their year-on-year changes are fairly synchronized, mitigating the concern that the world price index may not be representative of commodity prices faced by Argentina. We deflate the Grilli and Yang (1988) index to be a relative (“real”) price using an index of (US-dollar denominated) import prices for Argentina.10 Fig. 2, Panel (b) plots this time series in deviations from its sample mean. We focus on mean deviations rather than other detrending methods, since we are interested in capturing persistent movements over longer time spans, sometimes referred to as “supercycles” in commodity prices. We begin our characterization of the empirical regularities by documenting business cycle moments. We then turn to estimating an SVAR in order to gauge the dynamic effects of exogenous commodity price developments on Argentina’s economy. Furthermore, we present evidence on the relation of commodity prices and Argentina’s real interest rate spread. Finally, we summarize the insights of this section into a set of stylized facts.

2.2. Business cycle moments

Table 1 summarizes key business cycle moments of Argentina’s economy. We report mean, standard deviation, persistence, and contemporaneous cross-correlation of GDP growth, consumption growth, investment growth (all per capita), as well as the trade balance, defined as exports minus imports scaled by GDP. As the table shows, many properties of the Argentine business cycle are in line with what is typically observed in advanced economies. Output, consumption, and investment are strongly correlated and investment is much more volatile than output. On the other hand, there are features that are distinctive of fluctuations in emerging economies in avoiding default episodes by guiding policy. As will become clear, the model features a negative externality, as households do not take into account the effect of their borrowing on interest rates, which can lead to overborrowing.6

A similar argument is made by García-Cicco et al. (2010); they emphasize the importance of a long horizon to disentangle transitory shocks from shocks to trend growth in business cycles of emerging economies, which are the focus of Aguiar and Gopinath (2007). We will also aim at disentangling these two types of shocks in our model estimation, in addition to our focus on commodity prices.

5 Our model does not feature sovereign default or distress. While sovereign default episodes have been important for Argentina, we think there is a lot of merit in understanding the triggers of the cycles and how they are affected by external factors such as commodity prices in a relatively simple setting, which more realistically would end with a technical default. A better understanding of these regularities may actually help in avoiding default episodes by guiding policy. As will become clear, the model features a negative externality, as households do not take into account the effect of their borrowing on interest rates, which can lead to overborrowing.6

8 We extend the series of Ferreres (2005) to 2015. Compared to García-Cicco et al. (2010), we add another half decade of data. Details on the sources and construction of the data are provided in Appendix A.9

Argentina exports mainly agricultural and food commodities such as meat, maize, and soy beans, but to a lesser extent also petroleum, gold, and other non-food commodities.10

The import price index updates the series published by Ferreres (2005). We have tried alternative ways of deflating the commodity price series, for example using manufacturing prices (also expressed in US dollars), or the US consumer price index. The changes did not have a material impact on the results we present. We prefer the deflation using import prices (expressed in US dollars), since this brings the observed price index closest to the corresponding concept in our model, which is the relative price between commodities and a final tradable consumption good.
markets. In particular, it is worth highlighting that consumption growth is more volatile than output growth.\footnote{Interestingly, the excess volatility of consumption is smaller in our sample than in Garcia-Cicco et al.’s (2010) sample, suggesting that this phenomenon has attenuated in recent years.} Furthermore, as often observed in emerging markets, the trade balance is countercyclical. In the case of Argentina the contemporaneous correlation with observed in emerging markets, the trade balance is countercyclical.

A vector autoregression (SVAR): merging market business cycles, we consider the following structural

\[ A_0 Z_t = a t + A_1 Z_{t-1} + \ldots + A_p Z_{t-p} + u_t, \]

where \( Z_t \) is a vector containing the commodity price index in log deviations from mean, as plotted in Fig. 2, together with the log levels of the business cycle variables of interest - output, consumption, and investment; and \( Z_t \) is a vector of normally distributed structural shocks with covariance matrix \( E(u_tu_t') = I_5 \); and \( t \) is a linear time trend. We set the number of lags to \( p = 2 \).

We estimate the reduced form version of Eq. (1) using OLS, obtain the residuals \( \tilde{u}_t = A_0^{-1} u_t \) and then recover commodity price shocks, that is, the element of \( \tilde{u}_t \) corresponding to commodity prices, using restrictions on \( A_0 \). Our underlying identifying assumption is that international commodity prices are not contemporaneously affected by any other variable in the system. Given that Argentina is a relatively small country that should not be a driver of world-wide commodity prices, we believe this assumption is reasonable and justifies ordering the commodity price first in a Cholesky decomposition of the covariance matrix of \( u_t \).\footnote{This lag length is selected against \( p = 1 \) using various lag length selection criteria.}

Due to the imperfections in the measurement of commodity prices faced by Argentina discussed earlier, we focus solely on the IRFs of the SVAR, but do not resort to a forecast error variance decomposition. Our working assumption is that the IRFs in response to a shock identified from this specification give a meaningful representation of the dynamics following an exogenous shock to international commodity prices. However, we think that making quantitative statements about the total contribution of commodity prices to the variance of output from this exercise could be misleading given the noisy nature of the Grilich and Yang (1988) index as a measure of the actual price movements faced by Argentina. We instead carry out such a decomposition using the structural model in Section 5.

The impulse response functions to a one standard deviation shock to commodity prices are plotted in Fig. 3. The results show that there is a statistically and economically significant positive response of output, consumption, and investment. The total trade balance response is negative, that is, net exports fall in response to a commodity price increase. All responses are hump-shaped, peaking around two years following the shock, and quite persistent. Measured at peak, a one standard deviation shock in international commodity prices increases the level of real GDP per capita by more than one percent.

2.4. Commodity prices and interest rate spreads

What are possible channels behind the influence of commodity prices on emerging market business cycles? One key observation that has been highlighted in previous research on commodity exporting economies is the strong negative comovement of interest rate spreads and commodity prices. Fernàndez et al. (2015) highlight the strong negative effect of commodity price increases on country risk premia in sovereign bond spreads. Bastourre et al. (2012) estimate the correlation between a common factor of emerging economy bond returns and a common factor of commodity prices to be $-0.81$. Shousha (2016) emphasizes that the negative correlation is a major difference between emerging and advanced commodity exporters. Incorporating this effect into our analysis is important, since strongly countercyclical interest rate movements in general have been found to be a key driver of emerging markets business cycles, see for example Uribe and Yue (2006) and Neumeyer and Perri (2005).\footnote{This result connects with work on the procyclicality of capital flows and borrowing in emerging and developing economies. See for example Kaminsky et al. (2005).}

To shed further light on the link between the real spread and commodity prices in the case of Argentina, we run a set of regressions of the Argentine real interest rate spread on the real commodity price...
index (in log deviations from its mean). The regressions are specified as follows:

\[ r_t - r_t^* = \alpha + \xi (\ln \tilde{p}_t - \ln \bar{\tilde{p}}) + \beta X_t + \nu_t, \tag{2} \]

where \( r_t \) is the real interest rate of Argentina, \( r_t^* \) is a measure of the world interest rate, \( \tilde{p}_t \) is the commodity price (with \( \ln \tilde{p}_t - \ln \bar{\tilde{p}} \) being the log deviation from mean, which we plot in Fig. 2, Panel (b)), and \( X_t \) is a vector of control variables including output growth, the debt-to-GDP ratio and the trade balance. The key parameter of interest is \( \xi \), which denotes the sensitivity of the real interest rate spread with respect to changes in world commodity prices. Note that this sensitivity parameter will also feature in our model and we will calibrate it based on the results presented in this section. Since interest rate data for Argentina are not available over our baseline 1900–2015 sample, we stick to a smaller time period and try different interest rate series available. Specifically, we use the domestic lending rate, savings rate, and the money market rate, which are all provided by the IMF International Financial Statistics in nominal terms. To obtain a real measure we deflate these series using a corrected inflation index (in log deviations from its mean). These series are in nominal terms and normalized to the same value in 1962. Panel (b) displays the commodity price index of Grilli and Yang (1988), deflated with the Argentine import price index (in US dollars), and in log-deviations from its sample mean.

The baseline results are presented in Table 2. We show several other results using different interest rate measures in Appendix A. Our findings across all regressions, including those in the appendix, give negative point estimates of \( \xi \). These estimates are economically significant though not always statistically significant, likely due to the small sample. If we consider the smallest estimate (in absolute value) that is statistically significant, which is \(-0.199\), the interpretation is that a 10% deviation of commodity prices from their long-run mean can move Argentina’s real interest spread by almost 2 percentage points. We view this as strong evidence in support of a channel by which exogenous international commodity prices put downward pressure on interest rate premia faced by commodity exporting emerging economies. This evidence will guide our modeling choices below, where we also provide further theoretical discussion of this economic relation.

2.5. Summary of stylized facts

Based on the empirical analysis above, we summarize the following stylized facts around aggregate fluctuations in Argentina 1900–2015:

1. A relatively constant trend in GDP per capita growth at an average of 1.2% annually, with a relatively stable variance throughout the period.
2. Excess volatility of consumption over output.
3. A negative correlation between GDP growth and the trade balance.
4. Large of effects of commodity price shocks on all key business cycle variables.
5. A negative relation between interest spreads and commodity prices.

3. A two-sector small open economy model

We build on the small open economy model formulated by Aguiar and Gopinath (2007) and García-Cicco et al. (2010), which in turn...

Notes: GDP, consumption, and investment growth are real and in per capita terms. The trade balance is defined as total exports minus total imports, scaled by GDP. Persistence is the coefficient from an estimated AR(1) process. The frequency of the data is annual.
build on Mendoza (1991).16 Our model adds two elements absent in
their analysis. First it allows for a second sector to capture the dis-

Fig. 3. Impulse responses to 1 S.D. commodity price shock.

Note: The structural shock is identified using Cholesky ordering. 80% confidence bands are plotted, as suggested by Sims and Zha (1999). GDP, consumption, and investment are real, in per-capita terms and in log-levels. The trade balance is defined as exports net of imports divided by GDP.

In the production functions, \( a_t \) and \( \bar{a}_t \) capture total factor pro-
ductivities, which are exogenous and assumed to be stationary. \( X_t \) is the nonstationary level of labor-augmenting technology common to both sectors. We denote the gross growth rate of the nonstationary technology as \( g_t = X_t / X_{t-1} \), which is stochastic with mean \( g \). \( X_t \) is introduced to capture shocks to the trend, which has been a key focus in the literature on emerging market business cycles.17 The price of the final good is normalized to 1 and the price of commodities \( \bar{p}_t \) is exogenously given on world markets and subject to shocks. We assume that \( a_t \), \( \bar{a}_t \), \( g_t \), and \( \bar{p}_t \) follow stochastic processes which will be specified further below.

Firms in both sectors rent capital and hire labor in competitive input markets. The total stock of capital in the economy \( K_t \) is measured in final goods and is divided between the two production technologies, so that

\[
K_t = K^1_t + K^2_t. \tag{5}
\]

Capital depreciates at rate \( \delta \) and is accumulated through investment \( I_t \), which gives

\[
K_{t+1} = (1 - \delta) K_t + I_t. \tag{6}
\]

The economy is populated by a representative household who supplies the two types of labor, owns and rents out the capital stock, and borrows from abroad. The budget constraint is given by

\[
C_t + K_{t+1} + D_t + S_t + \frac{\phi}{2} \left( \frac{K_{t+1}}{K_t} - g \right)^2 = r^1_t K^1_t + r^2_t K^2_t + w^1_t N^1_t + w^2_t N^2_t + \frac{D_{t+1}}{1 + r_t} + (1 - \delta) K_t. \tag{7}
\]

Commodities can be produced domestically using capital \( K^2_t \) and labor \( N^2_t \); they can be used as an intermediate input in final goods production or traded on international markets. The production function in the commodity sector is

\[
Y_t = \bar{a}_t \left( K^2_t \right)^{\alpha_K} \left( \bar{M}_t \right)^{\alpha_{\bar{M}}} \left( X_t N^2_t \right)^{1 - \alpha_K - \alpha_{\bar{M}}}. \tag{3}
\]

\[
\bar{Y}_t = \bar{a}_t \left( K^2_t \right)^{\alpha_K} \left( X_t N^2_t \right)^{1 - \alpha_K}. \tag{4}
\]

In the production function, \( a_t \) and \( \bar{a}_t \) capture total factor pro-
ductivities, which are exogenous and assumed to be stationary. \( X_t \) is the nonstationary level of labor-augmenting technology common to both sectors. We denote the gross growth rate of the nonstationary technology as \( g_t = X_t / X_{t-1} \), which is stochastic with mean \( g \). \( X_t \) is introduced to capture shocks to the trend, which has been a key focus in the literature on emerging market business cycles.17 The price of the final good is normalized to 1 and the price of commodities \( \bar{p}_t \) is exogenously given on world markets and subject to shocks. We assume that \( a_t \), \( \bar{a}_t \), \( g_t \), and \( \bar{p}_t \) follow stochastic processes which will be specified further below.

Firms in both sectors rent capital and hire labor in competitive input markets. The total stock of capital in the economy \( K_t \) is measured in final goods and is divided between the two production technologies, so that

\[
K_t = K^1_t + K^2_t. \tag{5}
\]

Capital depreciates at rate \( \delta \) and is accumulated through investment \( I_t \), which gives

\[
K_{t+1} = (1 - \delta) K_t + I_t. \tag{6}
\]

The economy is populated by a representative household who supplies the two types of labor, owns and rents out the capital stock, and borrows from abroad. The budget constraint is given by

\[
C_t + K_{t+1} + D_t + S_t + \frac{\phi}{2} \left( \frac{K_{t+1}}{K_t} - g \right)^2 = r^1_t K^1_t + r^2_t K^2_t + w^1_t N^1_t + w^2_t N^2_t + \frac{D_{t+1}}{1 + r_t} + (1 - \delta) K_t. \tag{7}
\]

16 We abstract from nominal frictions and the important question of fixed versus nominal exchange rate choice. See for example Frankel (2004), and Mitchener and Pina (2016), who examine the costs and benefits of fixed exchange rates. For a modeling framework that incorporates nominal elements, we refer readers to Gali and Monacelli (2005) and the literature that built on their seminal contribution.

17 See in particular Aguiar and Gopinath (2007). The fact that in our model the nonstationary technology is common to both sectors ensures that the model admits a non-stochastic balanced growth path (BGP), as shown in Appendix C.

Note: The real spread is calculated by deflating the domestic lending rate, provided by the IMF, with a corrected inflation measure (see Cavallaro, 2013), and then subtracting the UK real rate. The commodity price is in log deviations from mean, as plotted in Fig. 2. Panel (b), Appendix A provides details on the sources of the other regressors.

Standard errors in parentheses

*** $p < 0.01$

** $p < 0.05$

* $p < 0.1$

where $C_t$ is final good consumption, $D_t$ denotes the level of (real) debt, and $\frac{\text{MT}}{\text{MT}}$ is newly issued debt at net interest rate $r_t$, $S_t$ is exogenous government spending, where $s_t = \frac{S_t}{X_t}$ will follow a stochastic process to be specified further below. $r_t$, $w_t$, $j = 1, 2$, are the returns from renting out capital and supplying labor to the two sectors, respectively. Note that in equilibrium the expected relative disutility of labor.

The first term of the spread in Eq. (9) is standard in the literature. Following Schmitt-Grohe and Uribe (2003), it is assumed that the premium is increasing in the (detrended) level of debt. The presence of $D_{t+1}$ is taken as exogenous by the representative household but $D_{t+1} = D_{t+1}$ holds in equilibrium. This debt-elastic interest rate ensures a stationary solution of the model after detrending.18

The second term determining the spread $r_t - r^*$ captures the robust empirical observation, discussed in detail in Section 2.4, that commodity prices strongly affect interest rate premia of commodity exporting economies. The parameter $\xi$ governs the sensitivity of the interest rate spread with respect to commodity price deviations from steady state and can be calibrated to the corresponding parameter we estimated in Section 2.4. Our approach here is to embed the relation between $r_t - r^*$ and $p_t$ in a reduced-form fashion, similar to Shousha (2016) and Fernández et al. (2015), who also document further empirical evidence in line with our findings. While we do not provide a complete formal rationalization of the relationship and focus mainly on the resulting implications for emerging economy business cycles, the link between commodity prices and interest rate premia can be derived from first principles following different approaches. Specifically, the negative relation between $r_t - r^*$ and $p_t$ may result from the effect of commodity prices on the country’s repayment capacity to international creditors. This could come in the form of a borrowing constraint, in which the value of the country’s collateral depends directly on commodity prices through export earnings. Creditors decrease the required interest rate premium when commodity prices increase, as the collateral value of the economy is higher.19 Min et al. (2003) provide empirical evidence for this particular channel, showing that export earnings and better repayment capacity bring down yield spreads. Alternatively, a possible mechanism could entail financial frictions in which domestic firms (rather than the government) borrow against collateral, which is positively linked to the terms of trade, and a relaxation in these constraints leads to a fall in credit spreads.20

Finally, the last term in the rate spread in Eq. (9) allows for a simple interest rate premium shock, similar to the one specified in García-Cicco et al. (2010). Since it is central to our objective to trace out the effects of commodity price movements for the economy, we also allow for the presence of $\mu_t$, in order to capture possible exogenously driven movements in the interest premium that are unrelated to commodity prices and thereby avoid hardwiring into the model that interest rate movements must be related to commodity prices. An alternative interpretation of this shock is of course an innovation in global interest rates (rather than the interest rate premium). We do not take a strong stance on this distinction in the analysis. From the domestic economy’s perspective, exogenous changes in the premium and the global interest rate have similar effects on the domestic interest rate.

Our modeling choice is arguably restrictive, as apart from commodity prices we only allow one additional shock to directly affect interest rates via the last term in the spread. This restrictiveness has the benefit of allowing a direct comparison of the relative importance of the mechanism we introduce vis-à-vis a collection of exogenous disturbances which are defined in the same way as in García-Cicco et al. (2010). These authors also estimate their model on Argentine data over a similar time period and their results therefore provide our preferred benchmark for the estimation results.

Eqs. (3) to (9) feature a set of exogenous disturbances to technology, preferences and prices, $\{a_t, \beta_t, g_t, h_t, r_t, \gamma_t, p_t\}$, which we specify to follow autoregressive processes in logs that are subject to stochastic shocks $\{\epsilon^t, \alpha^t, \beta^t, \xi^t, \phi^t, \psi^t\}$. The shocks are normally distributed with mean zero and standard deviations $\{\sigma_{\alpha}, \sigma_{\beta}, \sigma_{\epsilon}, \sigma_{\xi}, \sigma_{\psi}, \sigma_{\phi}\}$. The processes for $g_t$, $s_t$ and $p_t$ have deterministic mean different

18 See also Lubik (2007) for further discussion.

19 In Appendix E we formally illustrate this idea in a simple setting that gives rise to the postulated relation.

20 Akinci (2017), for example, generates a countercyclical country risk premium by introducing financial frictions in the spirit of Bernanke et al. (1999) to the economy’s firm sector. Her model does not feature a commodity sector, but an extension to include it seems natural. Fernández et al. (2015) allow future commodity prices to affect the spread. Justifying their modeling assumptions regarding the relation between spreads and commodity prices, they make very similar arguments to the ones we have provided here.
from 1 that are parametrized as \( g, s, \) and \( \tilde{p} \), and which will be calibrated to match business cycle moments of the steady state model. We specify autoregressive processes of order one for all shock processes, but allow the log of the commodity price \( \tilde{p} \) to follow an AR(2). This enables us to calibrate the parameters to the ones obtained from the SVAR analysis in Section 2.3. The processes are

\[
\ln(a_t) = \rho_a \ln(a_{t-1}) + \epsilon^a_t
\]

(10)

\[
\ln(\tilde{a}_t) = \rho_a \ln(\tilde{a}_{t-1}) + \epsilon^\tilde{a}_t
\]

(11)

\[
\ln\left(\frac{g_t}{g}\right) = \rho_g \ln\left(\frac{g_{t-1}}{g}\right) + \epsilon^g_t
\]

(12)

\[
\ln\left(\frac{y_t}{y}\right) = \rho_y \ln\left(\frac{y_{t-1}}{y}\right) + \epsilon^y_t
\]

(13)

\[
\ln((\gamma^2)_{t}) = \rho_{\gamma^2} \ln((\gamma^2)_{t-1}) + \epsilon^\gamma^2_t
\]

(14)

\[
\ln(\mu_t) = \rho_\mu \ln(\mu_{t-1}) + \epsilon^\mu_t
\]

(15)

and

\[
\ln\left(\frac{\tilde{p}_t}{\tilde{p}}\right) = \rho_{\tilde{p}} \ln\left(\frac{\tilde{p}_{t-1}}{\tilde{p}}\right) + \rho_{\tilde{p}}^2 \ln\left(\frac{\tilde{p}_{t-2}}{\tilde{p}}\right) + \epsilon^\tilde{p}_t.
\]

(16)

The model features the following resource constraints. In the final good sector the resource constraint is given by

\[
Y_t = C_t + I_t + S_t + \frac{\phi}{K} \left(\frac{K_{t+1}}{K_t} - g\right)^2 + TB_t
\]

(17)

where \( TB_t \) denotes the trade balance in final goods. The commodity market resource constraint reads as

\[
\tilde{p}_t \tilde{Y}_t = \tilde{p}_t \tilde{M}_t + \tilde{TB}_t,
\]

(18)

where \( \tilde{TB}_t \) denotes the real commodity trade balance, that is, net exports of commodities measured in terms of final goods. Carrying out some further national accounting, we compute the GDP and the total trade balance of the economy, both measured in terms of final goods, as

\[
Y^\text{GDP}_t = Y_t + \tilde{p}_t \tilde{Y}_t - \tilde{p}_t \tilde{M}_t
\]

(19)

\[
TB^\text{total}_t = TB_t + \tilde{TB}_t.
\]

(20)

The complete list of optimality conditions derived in this model is provided in Appendix C. The Appendix also contains the derivation of a normalized version of the model that is stationary, that is, where all variables that grow in equilibrium are divided by \( X_{t-1} \). This results in a stationary system in normalized variables, which we denote with lower case letters, and which we solve numerically with standard perturbation techniques. We carry out both a calibration exercise and a structural estimation of the model in order to assess the quantitative contribution of different shocks to fluctuations in the main macroeconomic aggregates.

### 4. Calibration and business cycle characteristics

The goal of this section is to study the business cycle characteristics of the model that are induced by shocks to the commodity price. To do so, we calibrate all structural parameters of the model, including the parameters governing the stochastic process of \( \ln(\tilde{p}_t) \).

We then generate impulse response functions, focusing exclusively on commodity price shocks.21

#### 4.1. Calibration

Table 3 summarizes our baseline calibration. Many of the parameter values are standard in business cycle research, but several are worth highlighting. Both the mean of the commodity sector productivity \( \tilde{\alpha} \), as well as the steady state relative price of commodities \( \tilde{p} \) can be adjusted to determine the relative size of the two sectors in the economy. We have normalized the mean technology in both sectors to 1 - as can be seen in Eqs. (10) and (11) - and find the value of \( \tilde{p} \) that matches the ratio of net exports of commodities to GDP observed in Argentina data (8.60%).22 This pins down the relative size of the commodity price sector that is in line with Argentine data. The parameter \( d^* \) in Eq. (9) is calibrated to match the average trade balance to output ratio in the data (3.04%, consistent with Table 1). We calibrate the mean of the exogenous spending process \( s \) to match the average government spending to GDP ratio observed in the data (9.38%). The parameter \( s \), which governs the sensitivity of the interest rate spread to commodity prices, is calibrated to the value obtained from the regressions in Section 2.4. To be conservative, we take the lower bound of \(-0.199\) among the statistically significant estimates we have obtained across a broad range of regression specifications. The average technology growth rate of the economy \( \tilde{\gamma} \) is set directly to 1.0117 in order to generate the observed mean output growth in the data. We impose equal capital shares in both sectors (\( \alpha_k = \alpha_m \)) and set the commodity share in the final goods production to \( \alpha_x = 0.05 \) following Shousha (2016). The parameter \( \psi \) is typically positive but close to zero in the small open economy literature (see e.g. Schmitt-Grohe and Uribe, 2003). The estimation results of García-Cicco et al. (2010), however, highlight that the data support a larger value of this parameter. In particular, a large value is necessary to generate a standard deviation of the trade balance roughly as big as the one of output growth and a decreasing autocorrelation function of the trade balance. We therefore set \( \psi = 2.8 \) in line with their posterior estimate.23 We set the adjustment cost parameter to \( \phi = 6 \), slightly higher than in one-sector models in the literature because...

21 We provide impulse responses functions to all other shocks in Appendix D.
22 To compute this target ratio in the data, we use a broad measure of commodity exports which includes manufactures of commodities. Due to data availability we use an annual sample starting in 1980.
23 In our estimation exercise we proceed similar to García-Cicco et al. (2010) and estimate \( \psi \).
this reduces the impact response of the economy to commodity shocks, which is needed to match our SVAR results (lower values would overstate the effect of commodity prices). The stochastic process of $\ln(\tilde{p}_t)$ is calibrated to be in line with the estimated SVAR coefficients in Section 2.3, which gives $\rho_1 = 0.95, \rho_2 = -0.13$, and $\sigma_\tilde{p} = 0.1064$.

4.2. Impulse response functions to commodity price shocks

Fig. 4 displays the impulse response functions to a one-standard deviation commodity price shock $\tilde{c}_t$, using the calibration described above. The figure shows that the responses on impact are in line with the stylized facts of the business cycle of Argentina highlighted in Section 2. Positive commodity price shocks boost the economy by increasing total output, consumption, and investment. The investment response is the strongest, and the consumption response is larger in magnitude than the output response. The total trade balance response is negative, rendering total net exports countercyclical.

To understand the mechanism behind the dynamics visible in Fig. 4, note that commodity prices in the model give rise to two effects. The first effect goes through commodity trade revenues. The economy needs to trade off the cost of more expensive commodity inputs in the production of final goods with the benefits of being able to produce and export commodities at higher prices (thus generating trade revenues). The second effect is governed by the negative sensitivity of the interest spread $r_t - r^*$ to commodity prices present in Eq. (9) and based on the empirical evidence in Section 2.4. Both of these effects are necessary to generate the responses in Fig. 4. To highlight this, Figs. 5 and 6 open up the double role of commodity prices in our model, by plotting impulse response functions for the two effects separately and inspecting them across the two sectors of the economy. In both cases, the responses of consumption and investment growth are omitted.

Fig. 5 studies the first effect of commodity price shocks, which we dub “competitiveness effect.” The figure plots the responses of GDP and the total trade balance to a commodity price shock when setting $\xi = 0$, that is, shutting off the channel through the interest rate, which we will analyze separately below. It also breaks down these responses into the dynamics in both sectors, that is, the final good sector and the commodity sector, separately. What the left panels of the figure reveal is that after a commodity prices increase, the value-added in the commodity sector increases significantly, as higher international prices make it attractive to increase production and exports. The final good sector actually suffers, as intermediate commodity inputs necessary to produce final goods become more expensive. This effect, however, is dwarfed by the boom in the commodity sector and total production in the economy increases. The trade balances in the two sectors, shown in the right panels of the figure, move in different directions. The economy starts exporting more commodities and importing final goods, as the former are very attractive to sell abroad and the latter less attractive to produce domestically. Looking at the two sectors together, the total trade surplus increases with the commodity price increase. This highlights that the first effect alone does not generate a countercyclical total trade balance, which is a salient feature in emerging economy business cycle data.

Fig. 6 shows the dynamics arising from the second effect, which we call “borrowing cost effect.” The figure plots the IRFs of total GDP and the total trade balance to a simple interest rate shock. This shock is (qualitatively) isomorphic to an increase in commodity prices that only goes through the presence of $\tilde{p}_t$ in Eq. (9) but that does not directly affect production in either sector. It thus completely shuts off the competitiveness channel described above and only shows the

---

24 Note that the literature in general gives little guidance on sensible values for $\phi$.

25 For the purpose of the comparison, the standard deviation of the interest rate shock is calibrated to have the same maximum output response as the total response in Fig. 4. The persistence is set to 0.9.
effect that commodity price have through the spread between the economy's borrowing rate and the world interest rate. As before, the figure breaks down the response by displaying the dynamics in each sector separately. The figure shows that the exogenous fall in borrowing rates allows households and firms to bring resources to the present by borrowing funds and decreasing the final good trade balance, that is, importing final goods. Some of these resources will be consumed (consumption goes up on impact, not shown in the figure), and some will be invested into capital (investment goes up on impact, not shown in the figure) in order to produce final goods and maintain a smooth path of consumption. Some of the capital will also be used to produce commodities, which are a required intermediary

\[ \text{Fig. 5. Breakdown of IRFs: no interest rate channel (} \xi = 0 \text{).} \]
\[ \text{Notes: Model impulse response functions to a one-standard deviation commodity price shock} \ \tilde{p}_t, \text{using the calibration described in the text but setting} \ \xi = 0. \]

\[ \text{Fig. 6. Breakdown of IRFs: pure interest rate shock.} \]
\[ \text{Notes: Model impulse response functions to a one-standard deviation interest rate shock} \ \epsilon_\ell, \text{using the calibration described in the text.} \]
input to final good production. This gives a slow and hump-shaped increase in the GDP of each sector and of the total economy. Hence, the total trade balance falls and output increases, but not on impact.

This lack of impact response in output stands in contrast with the empirical impulse responses and suggests that this channel alone cannot mimic the data.

In conclusion, the double-role of commodity prices in our model, through the joint impact of the competitiveness and the borrowing cost channels, gives rise to dynamics that are well in line with the empirical regularities observed in Argentina, as shown by comparing the SVAR results from Fig. 3 with the model responses presented in Fig. 4. This insight further highlights the importance of endogenously countercyclical spreads for aggregate fluctuations in commodity exporting economies, as recently also noted by Fernández et al. (2015) and Shousha (2016).26

We emphasize again that the focus of the calibration exercise in this section lies on explaining the dynamics that arises from commodity shocks alone. This is done to highlight our mechanism in light of the facts present in the data.27 In order to systematically gauge the fraction of aggregate fluctuations that can be accounted for by commodity price shocks, in comparison to all other shocks, we move on to estimating the model in the next section.

5. Estimation: assessing the quantitative contribution of different sources of shocks in emerging economies

In this section our goal is to assess the quantitative contribution of different shocks to aggregate fluctuations in emerging economies for which commodity exports are potentially important. To do so, we take the model to Argentine data and structurally estimate it with the goal of running a “horse race” between the various shocks that possibly drive the business cycle. We maintain the calibration of most of the parameters (see Table 3), and estimate the stochastic processes of the exogenous disturbances defined by Eqs. (10) to (16). In addition, we also estimate two key structural parameters. The first is at the heart of our mechanism: , which governs the sensitivity of the real interest rate spread to commodity prices. Estimating this parameter allows the data to speak about the strength of this mechanism within our model structure. Furthermore, we estimate , a parameter that governs the trade balance dynamics in the economy.28 In carrying out the estimation exercise, we give equal footing to all different shocks, which correspond to the candidate triggers previously proposed in the literature.

5.1. Estimation specification

We carry out a Bayesian estimation defining standard priors on the estimated parameters. We run a Markov Chain Monte Carlo (MCMC) algorithm to obtain draws from the marginal posterior distributions of the parameters.29 We then compute forecast error variance decompositions as well as historical variance decompositions of the observables at the estimated posterior modes. To estimate the model we add the following measurement equations

\[
\Delta \ln I_{t+1}^{\text{obs}} = \ln I_{t+1}^{\text{obs}} - \ln I_{t}^{\text{obs}}
\]

Table 4

where \( \Delta \ln I_{t}^{\text{obs}} \), \( \Delta \ln I_{t+1}^{\text{obs}} \), \( \Delta I_{t}^{\text{obs}} \), and \( \Delta I_{t+1}^{\text{obs}} \) correspond to the empirically observed time series which we analyzed in Section 2.30

The variables on the right hand side of Eqs. (21) to (24) are model concepts defined in Section 3.31 As explained above, we estimate the parameters governing the stochastic processes of all shocks, as well as \( \xi \) and \( \psi \) (all other parameters are calibrated as before). Table 4 summarizes the priors imposed on the parameters. As is standard in the estimation of DSGE models, we use beta priors on the persistence parameters and inverse-gamma priors on the standard deviations. The parameter values of the priors are the same as in Smets and Wouters (2007) and a number of related papers, except for the commodity price process. Since the latter is specified as an AR(2), we use priors that at the mode impose the same maximum root as for the other disturbances. We set identical scale parameters on the standard deviation of the shocks to remain agnostic about the relative importance of the different shocks. We put a normal prior on \( \xi \), which is centered around the smallest statistically significant regression estimate from Section 2.4, with the standard deviation equal to the standard error obtained from the regression. Finally, our prior on \( \psi \), also normal, is centered around the estimate obtained by García-Cicco et al. (2010).

5.2. Estimation results

How large is the contribution of different structural shocks to the variation in output, consumption, investment and the trade balance in emerging economies? We address this question using the results in Table 5. Panel (a) of the table shows the results of an (infinite horizon) forecast error variance decomposition based on the posterior estimates of our model using Argentine data from 1990 through to 2015.32 For each of the variables used as observables, this gives the share of variation that can be explained by a particular shock. We begin by focusing on the commodity price shock, as this

26 Recent work by Ben Zeve et al. (2017) and Farias and da Silva (2017) focuses on commodity price news shocks. These news shocks might also be connected with (and in fact be capturing) the interest rate effect, a link that deserves further exploration.

27 In Appendix D we report the IRFs to all of the other shocks we have defined in the model.

28 The importance of estimating this parameter has been stressed by García-Cicco et al. (2010).

29 We take 10 million draws. We discard the first 25% of draws and keep the remaining ones for inference. The acceptance ratio is 27.3%.

30 In principle we could add the commodity price series, which we used for parts of the calibration of the model, as an observable. However, since the Grilli and Yang (1988) may capture some dynamics unrelated to prices actually faced by Argentina, and an Argentina-specific index is only available for a much shorter sample, our preferred specification is to estimate the model without this observable and then compare the model-implied commodity price process with the empirically observed index. See the discussion further below.

31 Note that while we solve the (linearized) model in variables that are normalized by \( X_{t-1} \) (see Appendix C), we here use growth rates in the original non-normalized variables. This is possible, as the implied nonstationary variables can be recomputed from the model solution.

32 \( \rho_1 = 0.8 \) and \( \rho_2 = -0.15 \) imply that the larger root of the process 0.5, which is the same for an AR(1) processes with \( \rho = 0.5 \).

33 Table 8 in the appendix reports posterior mean and credible intervals of the individual parameters we estimate.
risk premia. This is in contrast with Chang and Fernandez (2013), who find that non- 
important in the context of a model that features financial frictions and time-varying 
stationary productivity shocks play a minor role relative to stationary TFP and interest 
studies feature a role for commodity prices.

Notes: Forecast error variance decomposition (at infinite horizon) of the observables used for estimation, calculated at the posterior modes. Stationary technology is the sum of the contribution of $a_t$ and $\hat{a}_t$. These estimates are obtained from the baseline estimation specification explained in the text.

is the main difference with respect to Aguiar and Gopinath (2007) and García-Cicco et al. (2010). As the table reveals, a sizable fraction of output (21.67%), consumption (24.02%) and investment growth (34.11%) can be explained by commodity price shocks. This confirms the intuition we derived from the calibration exercise and from the responses that were present in our SVAR analysis.

Turning to the other shocks, the table shows that our estimation attributes most of the variation in output growth (51.15%) to transitory technology shocks (the table reports the joint contribution of $a_t$ and $\hat{a}_t$). This finding is in line with García-Cicco et al. (2010). We do not, however, confirm their conclusion regarding the very small contribution of shocks to nonstationary technology and 61.11% in investment growth. The relative importance of other shocks remains broadly similar in this sample.

While we primarily focus on comparing our quantitative results to García-Cicco et al. (2010), as these authors use a similarly long sample for Argentina, our findings are also broadly in line with comparable recent work on commodity price shocks in emerging markets that

34 Interestingly, Akinci (2017) also finds both types of technology shocks to be important in the context of a model that features financial frictions and time-varying risk premia. This is in contrast with Chang and Fernandez (2013), who find that non-stationary productivity shocks play a minor role relative to stationary TFP and interest shocks, broadly confirming the results of García-Cicco et al. (2010). None of these studies feature a role for commodity prices.
Fig. 8. Historical decomposition of Argentine output growth 1900–2015.
Note: The line displays the actual time series of real GDP per capita growth, which is used as one of the observables in the estimation. The bars represent the contribution of different shocks to the movements in this series at a given point in time. The estimates are obtained using the baseline estimation specification explained in the text. "Other" includes $\nu$, $s$, $\mu$ and the contribution of initial values, which is negligible.

has estimated quantitative models on shorter samples. Fernández et al. (2015), for example, estimate that the share of commodity shocks in the variance of real output across a number of emerging economies is 42%, a number that is very similar to our post-1950 estimate.

In addition to the decomposition given in Table 5, which is a theoretical object computed at the posterior modes, it is also possible to construct a historical variance decomposition that breaks down the movements of a variable at a given point in the actual data sample into the contribution of the different shocks. Fig. 8 presents such a decomposition for Argentine output growth from 1900 to 2015. The black line displays the actual time series of growth in real GDP per capita, which is used as one of the observables in the estimation. The bars represent the contribution of different shocks to the movements in the output time series at given points in time. Overall, the figure mirrors the insights from Table 5, given that commodity price shocks and technology shocks (of both types), capture most of the variation in output growth. Fig. 8, in addition, enables us to inspect particular episodes in the economic history of Argentina, as scrutinized for example by Taylor (2014), and interpret them through the lens of our model.

Taken altogether, our results suggest that commodity prices should feature prominently in the analysis of business cycles in emerging economies. In terms of quantitative contribution, we find that they are among the three most important shocks in driving output growth in Argentina. Importantly, shocks to international commodity prices, in contrast to inherently very different concepts such as domestic TFP shocks, are easier to measure and identify, and eventually act upon, by policy makers.

5.3. Further discussion: measurement of GDP

How “direct” is the effect of commodity price variation on real GDP? The relative price $p_t$ directly enters the calculation of real GDP in our model, but national accounting techniques in practice may not reflect the full variation in relative prices in the way our measurement
Eq. (19) prescribes.\textsuperscript{35} It is therefore of interest to break down the variation in GDP resulting from commodity price fluctuations into the share that comes directly from $\tilde{p}_t$ and the share that arises from the endogenous changes in quantities following commodity price changes. This latter effect on quantities would be the only source of change in measured real GDP if the statistical office kept prices constant in its measurement. If this share of the variation is important, then the effect of commodity price shocks on GDP that we measure would be more robust to the specific measurement of real GDP in practice.

To study this question, Fig. 10 in the Appendix plots two alternative measures of GDP from a simulation exercise. The exercise consists of feeding observed commodity prices into the model, holding all other disturbances constant, and then computing two alternative GDP measures. The first measure is $Y_{t}^{GDP}$ computed as in Eq. (19), whereas the second one, $Y^{GDP}_t$, computes the economy's GDP holding commodity prices fixed at their steady state value $\bar{p}$, that is,

$$Y_{t}^{GDP} = Y_t + \bar{p} \tilde{Y}_t - \bar{p} \hat{M}_t. \quad (25)$$

The figure shows that the two resulting series are very similar, and the variation in $Y^{GDP}_t$ accounts for most of the variation in $Y_{t}^{GDP}$.\textsuperscript{36} This highlights that the economy's endogenous dynamics in response to changes in international commodity prices accounts for the major bulk in the variation of total real value added. This makes the results in our paper robust to different methods used to measure real GDP.

6. Conclusion

This paper has sought to answer a classical question in International Macroeconomics: what causes the large swings in economic activity in emerging markets? The literature has proposed a variety of triggers, but remains split on the answers. We study the question anew, combining a model that nests the previous sources of shocks advanced in the literature and historical data for Argentina going back to 1900.

The model features two key elements. First, it allows for a second sector to capture the separate role of commodities in the economy. Specifically, the analysis focuses on the case of a net commodity exporting country, facing exogenous price changes. Second, the model embeds a negative relation between the interest rate premium and commodity prices, which is consistent with the empirical evidence. Exogenous increases in commodity prices improve both the competitiveness of the economy and its borrowing terms through the negative effect of higher prices on the spread between the country's borrowing rates and world interest rates. Both effects jointly result in strongly positive effects of commodity price movements on GDP, consumption, and investment, and a negative effect on the total trade balance. They also generate an excess response of consumption over output.

We estimate the model using data on Argentina from 1900 to 2015 to provide a quantitative evaluation of the various sources of shocks and their effect on macroeconomic aggregates. Our estimate of the contribution of commodity price shocks to fluctuations in output growth of Argentina is in the order of 22%. Furthermore, commodity prices account for 24% and 34% of the variation in consumption and investment growth, respectively. The contribution of these shocks is even bigger on a post-1950 data sample, accounting for 38% of the variance of output growth, 42% of consumption, and 61% of investment. We also find a role for non-stationary productivity shocks - albeit much smaller than the one documented in Aguiar and Gopinath (2007), though bigger than García-Cicco et al. (2010) - and an important role for stationary productivity shocks, consistent with previous findings.

Though in this paper we do not address normative issues, the results offer hope. Insofar as part of the cycle can be accounted for by observable variables (international commodity prices) that cannot be manipulated for political goals, contingent macroeconomic policies can be designed to help mitigate the cycle. Given the nature of the driver, sovereign wealth funds may offer a promising avenue for tackling volatility in commodity producing countries like Argentina. A proper normative analysis would require, at a minimum, an extension of the model to incorporate default, a task we leave for future work.

Appendix A. Details on data

A.1. GDP and its components

Data on real GDP, Investment, Consumption, Government Spending and Net Exports from 1900 through to 2009 come from Ferreres (2005) - Ferreres has extended these series to 2009. We extend the data further to 2015 using the corresponding series from the Argentine Finance Ministry "Ministerio de Economía (Ejecución Presupuestaria de la Administración Nacional),” available online. The growth rate of the latter series was applied to Ferreres' 2009 figure.

A.2. Commodity prices

Data on world commodity prices are based on the Grilli and Yang (1988) commodity price index series updated by Pfaffenzeller et al. (2007), which runs from 1900 through to 2011. We update the series to 2015, following Pfaffenzeller et al.’s (2007) procedure.

The Argentina-specific price index is constructed using Argentine export weights available in the UN Comtrade data base. We match these weights with commodity-specific price indexe provided by the World Bank. This is done for the broad commodity categories fuel, timber, food, beverages and fertilizer from 1962.

As a deflator for the commodity price series we use the index of US-dollar import prices for Argentina provided by Pfaffenzeller et al. (2007), which we update till 2015 using the figures from INDEC. For robustness we also tried manufacturing prices (expressed in US dollars), and the US consumer price index, available via FRED. The results remain broadly unchanged using these deflators.

A.3. World real interest rate

To measure global real interest rates we use the UK nominal interest rate series published by the Bank of England from 1900 through 2015 and subtract the UK inflation rate provided by the UK Office for National Statistics (ONS).

\textsuperscript{35} This could be due to base-year pricing, chain-linking or simply due to price mismeasurement or interpolation. Kehoe and Ruhl (2008), for example, argue that changes in the terms of trade have no first-order effect if output is measured as chain-weighted real GDP.

\textsuperscript{36} The R-squared from regressing one series on the other is 0.95.
A.4. Domestic real interest rates

We use the nominal domestic lending rate, savings rate and money market rate, provided by the IMF International Financial Statistics. We deflate these series using the corrected inflation measure available at http://inflacionverdadera.com/. See Cavallo (2013) for a discussion.

A.5. Government debt

Data on Debt-to-GDP ratios come from Argentina’s national statistical office, INDEC (Online, Table 7.10).

Note: The real spread is calculated by deflating the money market rate, provided by the IMF, with a corrected inflation measure (see Cavallo, 2013), and then subtracting the UK real rate. The commodity price is in log deviations from mean, as plotted in Fig. 2, Panel (b). Appendix A provides details on the sources of the other regressors.

Appendix C. Model details

C.1. Optimality conditions

C.1.1. Firms

The first-order conditions for final goods producers with respect to $k_t^2$, $N_t^2$ and $M_t$ are

$$r_t^2 = \alpha_k a_t \left( \frac{k_t^2}{N_t^2} \right)^{\alpha_K - 1} \left( M_t^{-1} \right)^{\alpha_M - \eta} \left( X_t N_t^2 \right)^{1 - \alpha_K - \alpha_M}$$

The first-order conditions for commodity producers with respect to $k_t^1$ and $N_t^1$ are

$$r_t^1 = \alpha_k a_t \left( \frac{k_t^1}{N_t^1} \right)^{\alpha_K - 1} \left( M_t^{-1} \right)^{\alpha_M - \eta} \left( X_t N_t^1 \right)^{1 - \alpha_K - \alpha_M}$$

C.1.2. Representative household

Setting up the dynamic Lagrangian

$$
\mathcal{L} = \sum_{t=0}^{\infty} \nu_t \beta^t \left[ C_t - \theta a^{1 - X_t} (N_t^1)^{\alpha_1} - \theta a^{-1} X_t (N_t^2)^{\alpha_2} \right]^{1 - \gamma} - 1
$$

$$
- X_t^{-1} \lambda_t \left[ C_t + D_{t+1} + K_{t+1}^1 + K_{t+1}^2 + 2 \left( \frac{K_{t+1}^2}{K_t^2} - 1 \right) \right]
$$

the first-order conditions with respect to $C_t$, $N_t^1$, $N_t^2$, $D_{t+1}$, $K_{t+1}^1$, and $K_{t+1}^2$ are derived as follows:

$$
C_t - \theta a X_{t-1} (N_t^1)^{\alpha_1} = \lambda_t X_{t-1}^{-\gamma}
$$

$$
C_t - \theta a X_{t-1} (N_t^1)^{\alpha_1} - \theta a^{-1} X_{t-1} (N_t^2)^{\alpha_2} = \lambda_t X_{t-1}^{-\gamma} w_t
$$

$$
C_t - \theta a X_{t-1} (N_t^1)^{\alpha_1} = \lambda_t X_{t-1}^{-\gamma} w_t
$$

$$
C_t - \theta a X_{t-1} (N_t^1)^{\alpha_1} - \theta a^{-1} X_{t-1} (N_t^2)^{\alpha_2} = \lambda_t X_{t-1}^{-\gamma} w_t
$$

$$
\nu_t \lambda_t X_{t-1}^{-\gamma} = \beta (1 + r_t) X_t^{-\gamma} \nu_{t+1} (1 + \lambda_{t+1})
$$
conditions (32) to (37) can be rewritten in stationary form as:

\[
v_t \lambda_t \gamma \left[ 1 + \phi \left( \frac{k_{t+1}^c}{K_t^c} - \tilde{g} \right) \right] = \beta_t \gamma \left[ v_{t+1} \lambda_{t+1} + \frac{1}{2} \left( \frac{k_{t+2}^c}{K_{t+1}^c} - \tilde{g} \right)^2 \right] (36)
\]

\[
v_t \lambda_t \gamma \left[ 1 + \phi \left( \frac{k_{t+1}^m}{K_t^m} - \tilde{g} \right) \right] = \beta_t \gamma \left[ v_{t+1} \lambda_{t+1} + \frac{1}{2} \left( \frac{k_{t+2}^m}{K_{t+1}^m} - \tilde{g} \right)^2 \right] (37)
\]

Note that Eqs. (36) and (37) imply that the expected return on capital is equalized across the two sectors in the economy.

C.2. Stationary version of equilibrium

Imposing market clearing and denoting \( c_t = \frac{c_t}{x_t^c}, k_t^1 = \frac{k_t^1}{x_t^c}, k_t^2 = \frac{k_t^2}{x_t^c}, \) etc., and using the fact that \( g_t = x_t^c/x_t^l, \) the first-order conditions (32) to (37) can be rewritten in stationary form as:

\[
\left[ c_t - \theta \omega^{-1} \left( N_t^l \right)^{\alpha_l} - \theta \tilde{g}^{-1} \left( N_t^c \right)^{\alpha_c} \right]^{-\gamma} = \lambda_t
\]

\[
\left[ c_t - \theta \omega^{-1} \left( N_t^l \right)^{\alpha_l} - \theta \tilde{g}^{-1} \left( N_t^c \right)^{\alpha_c} \right]^{-1} \theta \left( N_t^c \right)^{\alpha_c-1}
\]

\[
= \lambda_t \left( \frac{1-\alpha_c-\alpha_l}{(1-\alpha_c-\alpha_l)} a_t \left( k_t^1 \right)^{\alpha_c} (\tilde{m}_t)_{\alpha_l} \left( N_t^l \right)^{-\alpha_l-\alpha_l} (40) \right)
\]

\[
\left[ c_t - \theta \omega^{-1} \left( N_t^l \right)^{\alpha_l} - \theta \tilde{g}^{-1} \left( N_t^c \right)^{\alpha_c} \right]^{-\gamma} = \lambda_t \left( \frac{1-\alpha_c}{(1-\alpha_c)} \tilde{p}_t \tilde{a}_t \left( k_t^1 \right)^{\alpha_c} \left( N_t^c \right)^{-\alpha_c} \right)
\]

The remaining equations of the system that define the stationary equilibrium are given by the budget constraint (with factor prices eliminated), the production functions and the interest rate equation, all normalized in the same way, i.e. by

\[
c_t + k_{t+1}^l g_t + \tilde{p}_t \tilde{m}_t + d_t + s_t + \frac{\phi}{2} \left( \frac{k_{t+1}^c}{k_t^c} - \tilde{g} \right)^2 = y_t + \tilde{p}_t \tilde{y}_t + (1-\delta) \tilde{k}_t
\]

\[
y_t = a_t \left( k_t^1 \right)^{\alpha_c} (\tilde{m}_t)_{\alpha_l} \left( N_t^l \right)^{1-\alpha_c-\alpha_l} \]

\[
r_t = r^* + \psi \left( e^{d_t+d^*} - 1 \right) - \xi (\log (\tilde{p}_t) - \log (\tilde{\rho})) + \left( e^{\theta-1} - 1 \right)
\]

and by the stochastic processes (10) to (16) in the body of the paper. The total trade balance and GDP of the economy can be calculated accordingly.

C.3. Steady state

To compute the steady state, we can proceed as follows:

1. Drop all time subscripts.
2. Steady state must fulfill \( r^* = \frac{1}{2} \delta e^{-\gamma} - 1 \) and \( d = d^* \) from Eqs. (41) and (48).
3. Solve Eq. (44) for the steady state capital-labor ratio in the commodity sector as a function of primitives.
4. Combine Eqs. (38) and (39) through \( \lambda \). Plug in the capital-labor ratio. It is possible to solve analytically for \( N^l \) as a function of primitives. Using the capital-labor ratio, can solve for \( k_t^1 \).
5. Combine Eqs. (38), (40), (42), and (43) to eliminate \( \lambda, k_t^1, \tilde{m} \). Obtain an equation for \( N^l \) as an implicit function of primitives. Solve this equation for \( N^l \) numerically.
6. Use the equations combined in the previous step to solve for \( k_t^1 \) and \( \tilde{m} \) given the solution for \( N^l \).
7. Use the budget constraint to solve for \( c_t \).
Appendix D. Additional model results

(a) Final goods sector productivity shock $\epsilon_t^1$

(b) Commodity sector productivity shock $\epsilon_t^2$

(c) Growth shock $\epsilon_t^3$

(d) Commodity price shock $\epsilon_t^4$

(e) Interest rate shock $\epsilon_t^5$

(f) Spending shock $\epsilon_t^6$

(g) Preference shock $\epsilon_t^7$

Fig. 9. Impulse response functions to different shocks.
Note: All shocks have been re-scaled to give the same maximum GDP growth response as the commodity price shock in the body of the paper.
Appendix E. Interest rate premia and commodity prices: simple formal illustration

Suppose there is a borrower who borrows amount \( D_t \). With probability \( 1 - \lambda \) only a repayment smaller than the borrowed amount \( D_t \) can be made. This repayment is a fraction \( \phi \) of commodity output \( p_t y_t \) (equivalently, \( p_t \hat{y}_t \) can be thought of as collateral which the lender can seize when full repayment is not possible). The presence of a risk-neutral lender who herself can obtain funds at the risk-free rate \( r^* \) and who faces perfect competition, will result in the following zero profit condition:

\[
(1 + r^*)D_t = \lambda(1 + r_t)D_t + (1 - \lambda)\phi p_t \hat{y}_t, \tag{1}
\]

which can be rearranged to

\[
r_t = \frac{1 + r^* - 1}{\lambda} \frac{\phi}{\lambda D_t} \hat{p}_t y_t - 1. \tag{2}
\]

As can be seen from Eq. (2), an increase in \( \hat{p}_t \) reduces the interest rate \( r_t \), ceteris paribus. This is the key assumption of our model we aim to rationalize with the above illustration. Furthermore, and also consistent with our formulation in Eq. (9), \( r_t \) is increasing in the level of debt \( D_t \).
